The GaAsFET transistor requires special handling care because it is especially sensitive to static electricity. Solder the transistor into the circuit last; use a grounded-tip, low-temperature soldering iron. If a static-free work station is unavailable, ground yourself before removing the MGF1402 from its protective package to prevent static buildup from destroying the device.

Although an MGF1402 is specified, you can use other devices if you change the biasing resistors accordingly. Consult the references listed at the end of this project writeup before attempting a substitution. The MGF1402 is a fairly common transistor and is available from several of the suppliers listed in Chapter 35.

The general layout is shown in Fig. 57. Although BNC connectors were used here, Type-N or SMA connectors may be employed. A number of ground feedthroughs are used at points indicated on the schematic diagram. These feedthroughs are necessary for stable operation and optimum performance; they must be used. See Fig. 54.

Ceramic chip capacitors are mandatory for the source bypass on the MGF1402. Do not attempt to substitute low-grade capacitors here! Chip capacitors provide a low-impedance source ground; this is of particular importance for stable operation with high-gain devices such as the microwave GaAsFET used here. The MGF1402 is mounted directly to the source bypass capacitors by its source leads. First, solder one end of each chip capacitor to the ground plane. Then solder one source lead to each chip capacitor. See the preamplifier projects that appear earlier in this chapter for complete details of this mounting scheme.

The output filter is similar to the one described in the local-oscillator section. In

Fig. 58 — Closeup of the 28-MHz post amplifier. Q1 uses a push-on finned heat sink. The transistor case is tied to the collector, so the heat sink must be positioned away from the case and nearby components.

Fig. 59 — Closeup of the receive mixer and diplexer filter. RG-174 cable is used between the mixer and input connectors.

this case, however, the coupling capacitor is a 0.3- to 3-pF trimmer. A toroidal coil is added for the 164-MHz image trap.

### 28-MHz Post Amplifier

The 2N5109 post amplifier shown in Fig. 58 requires little special care. Note, however, the use of a push-on, finned heat sink. Keep the heat sink away from the circuit board and other components since the 2N5109 case is tied to the transistor collector.

### Receive Mixer

The receive mixer and diplexer filter may be housed in one enclosure, as shown in Fig. 59. The SRA-1H is best mounted on top of the circuit board with the pins protruding through to the component side. Carefully mark and drill eight holes using

a no. 59 drill bit. All holes on top of the board are deburred with a 1/8-inch drill bit; turn the bit by hand to remove the copper from around the hole. This allows for ample clearance where leads are close to touching the board. Deburr the holes for pins 1, 3, 4 and 8 on the component side of the board. The other pins are grounded and should be soldered directly to the ground plane.

### Transmit Converter

Construction of the transmit converter requires a little extra planning for component layout because of the number of stages involved. Position the SRA-1 and the five transistors to allow sufficient room for the remaining components. It is better to allow extra room than to be cramped for space. Refer to Fig. 60 for ideas on board layout.

Fig. 60 — The transmit converter incorporates extensive bypassing and shielding. J1 and J2 are at the bottom left. Q1, Q2 and Q3 are arranged along the lower edge of the board, below the horizontal shield. Q4 and Q5 are above that shield; Q4 is to the right. The two emitter leads of Q5 are soldered directly to the ground plane near the center of the board. The low-pass filter is between Q5 and the output connector.

Drill any mounting holes as you go along. Start by mounting the SRA-1 using the same technique described above. Then mount J1 and J2. Build the mixer band-pass filter first, and then work stage-by-stage toward the output.

Q1, Q2 and Q3 should be shielded by placing a small piece of sheet metal or double-sided circuit-board material over each transistor. Cut a U-shaped notch in the shield to clear the transistor case. Each shield may be soldered directly to the ground plane. Q1 and Q2 are mounted "belly up," while Q3 and Q4 are mounted "right side up." Cut the Q3 and Q4 emitter lead to  $\frac{1}{4}$  inch before soldering the transistor in place. Note that Q1 and Q2 have four leads; one is tied directly to the transistor case and must be soldered to the ground plane. The case of Q3, however, is connected to the collector, so be sure to leave adequate clearance between the case and the shield. Q4 must have a push-on, finned heat sink. The heat sink should not touch any other components. Again, keep all leads as short as possible.

Q5 is a stud-mounted power transistor. Drill a hole just large enough to pass the threaded stud and transistor base through the circuit board. The emitter leads should lay almost flat on the component side of the board. Cut the collector and base leads to half of the original length, while leaving the emitter leads full length. The heat sink for Q5 is made from a U-shaped piece of brass sheet (the same material used for the circuit-board shields). Mount D1 on top of the heat sink for good thermal contact;

Fig. 61 — Space is a bit tight, but the 10-W amplifier will fit inside a small diecast box. Q1 is mounted at the center of the board. Input circuitry is to the left, output to the right. U1 and associated bias circuitry are behind the shield adjacent to J1.

solder the ground end of D1 directly to the heat sink.

The value of R1 must be determined experimentally. Start with a 68-ohm, 2-W resistor. Measure the quiescent current of Q5 by inserting a milliammeter in the circuit at the cold end of L8. The quiescent current should be between 20 and 40 mA; adjust the value of R1 until proper bias is achieved.

The transmit converter is tuned by applying 12.5-V dc, LO energy and a 28-MHz signal attenuated to provide -10 dBm at

the mixer input. Peak the double-tuned filter for maximum 220-MHz (or 144-MHz) output. If a spectrum analyzer is available, tune for a balance between maximum 220-MHz (or 144-MHz) energy and minimum spurious output. Next, peak C1 through C3. Alternately peak C5 and C6 for maximum output. C7, C8, C9 and C10 are adjusted in the same manner. Although a wattmeter may be used for tuning purposes, a spectrum analyzer tells the full story. Tune each stage for a compromise between output power and spectral purity.

Harmonics are 60-dB down after filtering. After you're through adjusting the transmit converter, power output should be 1 watt.

#### Power Amplifier

The 10-W amplifier shown in Fig. 61 is mounted in its own diecast box. Ground feedthroughs are used beneath the 2N5946 emitter leads and at all variable capacitor grounds. The LM317 regulator IC must be attached to a heat sink. Bias should be adjusted for a quiescent current of 40 to 60 mA.

C5, C6 and C7 are Unelco metal-clad book-mica capacitors. These capacitors provide an excellent low-impedance RF ground and are designed to work at high-current points. For stable operation, it is important that you use book-mica capacitors at these points.

The heat sink is fashioned from two U-shaped pieces of aluminum sheet. Be careful when mounting the heat sink; lateral pressure on the 2N5946 stud may break the transistor.

#### Summary

The transverter modules are arranged on a chassis as shown in Figs. 40 and 62. Short runs of 50-ohm coaxial cable interconnect the units. Most of the dc power wiring is done underneath the chassis.

The 144/220-MHz transverter represents a low-cost, modern approach to getting on the VHF bands. Circuit construction is straightforward, and the design makes use

Fig. 62 — The transmit converter is mounted in a cutout portion of the chassis, component side down. Dc for the transmit and receive chains is brought in to K1 and from there to a barrier strip. Wires are routed from the barrier strip to each module.

of commercially available parts. The modular construction approach offers flexibility for easy troubleshooting and experimentation.

The author wishes to thank Ron Whitsel, WA3AXV, and other members of the Mount Airy VHF Radio Club "Packrats"

whose encouragement made this project possible.

# 144- or 220-MHz Band-Pass Filter

Spectral purity is necessary during transmitting. Tight filtering in a receiving system ensures the rejection of out-of-band signals. Those unwanted signals may otherwise lead to receiver overload and increased intermodulation-distortion (IMD) products that manifest themselves as annoying in-band "birdies."

The double-tuned band-pass filter is not new. Filter designs involving this circuit abound in amateur designs because they are simple, are easy to construct, offer a relatively narrow passband and are quite forgiving of resonator variations. This filter was designed by Paul Drexler, WB3JYO.

The filter shown in Fig. 77 includes a resonant trap coupled between the resonators to provide increased rejection of undesired frequencies. Many popular VHF conversion schemes use a 28-MHz intermediate frequency (IF).

Proper filtering of the image frequency is often overlooked in amateur designs. The low-side injection frequency used in 144-MHz mixing schemes is 116 MHz and the image frequency, 88 MHz, falls in the

Fig. 77 — Schematic diagram of the double-tuned band-pass filter. Component values are given in Table 2.

Fig. 78 — Frequency-response of the 144-MHz band-pass filter. Image-reject notch is for a 28-MHz IF.

Fig. 79 — Frequency-response of the 220-MHz band-pass filter. Image-reject notch is for a 28-MHz IF.

Channel 6 television band. Inadequate rejection of a broadcast carrier at this frequency results in a strong, wideband signal present in the low end of the two-meter band. A similar problem exists on the transmit side that can cause TVI. The band-pass filters described have been effectively used to suppress undesired mixing products. See Figs. 78 and 79.

Circuit construction is easily accomplished using a double-sided copper-clad circuit board. Observing good construction techniques, component lead lengths must be kept to a minimum to eliminate resistive losses and unwanted stray coupling. The piston trimmers are mounted through the board with the coils soldered to the opposite end, parallel to the board. Placing a shield between L1 and L3 decreases mutual coupling and improves the frequency response. Peak C1 and C3 for optimum response. Component values are given in Table 2.

Table 2

## Component Values

	144 MHz	220 MHz
C2	1 pF	1 pF
C1, C3	1-7 pF piston	1-7 pF piston
L2	27t no. 26 enam. on T37-10	15t no. 24 enam. on T44-10
L1, L3	7t no. 18, 1/4-in ID, tap 1 1/2t	4t no. 18, 1/4-in ID, tap 1 1/2t

L1, C1, L3 and C3 form the tank circuits that resonate at the desired frequency. C2 and L2 reject the undesired energy while allowing the desired signal to pass. The tap points on L1 and L3 are for 50-ohm matching and may be adjusted for optimal energy transfer. Several filters have been constructed using a miniature variable capacitor in place of C2 so that the notch frequency could be varied.

# RF Chokes for the VHF Bands

Many of the construction projects in this chapter call for fabricating one or more RF chokes. Specific instructions are given in each case, but additional guidance is often sought by those embarking on projects of their own design. The information presented here is a brief tutorial in theory and practice for those interested in constructing VHF equipment.

Distributed capacitance limits the range over which an RF choke will work. A coil wound with some spacing between the adjacent turns exhibits less distributed capacitance than one in which turns are close. This makes the space-wound choke superior to the close-wound one. A minimum of cement on the windings is also desirable. The space-wound 50-MHz choke in Table 3 and shown in the upper right of Fig. 80 is as good as you can make for that band, and better than most chokes you could buy. It is good at 144 MHz as well, and even serviceable at 220 MHz. A close-wound choke of fine wire, heavily doped with lacquer, might be usable on only one VHF band, and very likely it would not be too good even there.

To construct RF chokes you will need some wire: no. 22 enamel (Nyclad or Formvar preferred); no. 28 enamel, silk or cotton covered; and no. 30 or 32, of any similar insulation. Silk- or cotton-covered wires take cement nicely, but enamel is okay otherwise, and it is usually most readily available.

High-value  $\frac{1}{2}$ - or 1-watt carbon resistors make good winding forms for use at 144 MHz and higher. A 2-watt resistor is big enough for a 50-MHz choke, but Teflon or Nylon rod stock is better. Do not use polystyrene or Lucite, if any heat is to be involved. These materials will melt in the heat of an average transmitter enclosure.

Fig. 80 — Typical handmade VHF chokes. At the rear are close-wound and space-wound chokes for 50 MHz wound on  $\frac{1}{4}$ -inch and  $\frac{1}{2}$ -inch Teflon rod, drilled and tapped for end-mounting. Three 144-MHz chokes are shown in the center; the two at the left being excellent for high-current applications. In front are similar types to these, but for the 220-MHz band.

Table 3

RF Chokes for 50-, 144- and 220-MHz Service

Frequency	Inductance	Description
50 MHz	7.8 to 9.5 $\mu$ H	B&W miniductor no. 3004, 1-3/8 to 1-9/16 inch long.*
50 MHz	8.3 $\mu$ H	No. 28 double silk covered (dsc), space-wound on $\frac{1}{2}$ -inch Teflon rod. Winding 1 $\frac{1}{4}$ inch long. See text.
50 MHz	7.2 $\mu$ H	No. 28 dsc, close-wound on $\frac{1}{4}$ -inch Teflon rod. Winding 1-7/16 inch long.
144 MHz	2.15 $\mu$ H	No. 22 Nyclad, close-wound 1-3/16 inch on $\frac{1}{4}$ -inch Teflon rod.
144 MHz	1.42 $\mu$ H	31 turns no. 28 dsc, space-wound on $\frac{1}{4}$ -inch dia self-supporting.
(The 144-MHz chokes work well on 220 MHz.)		
220 MHz	0.6 $\mu$ H	13 turns no. 22 Nyclad on $\frac{1}{4}$ -inch Teflon rod.
220 MHz	0.75 $\mu$ H	17 turns no. 28 dsc space-wound on $\frac{1}{4}$ -inch Teflon rod. Winding 5/8 inch long.
220 MHz	0.52 $\mu$ H	22 turns no. 22 Nyclad close-wound on no. 24 drill, self-supporting.

\*Excellent for use except where high temperatures are involved.

Fig. 81 — How a choke is positioned with respect to other circuits may be important. The choke at the top is coupled to the plate line of the transmitter tuned circuit. Outside the loop, as shown at the bottom, makes the choke far less subject to RF breakdown.

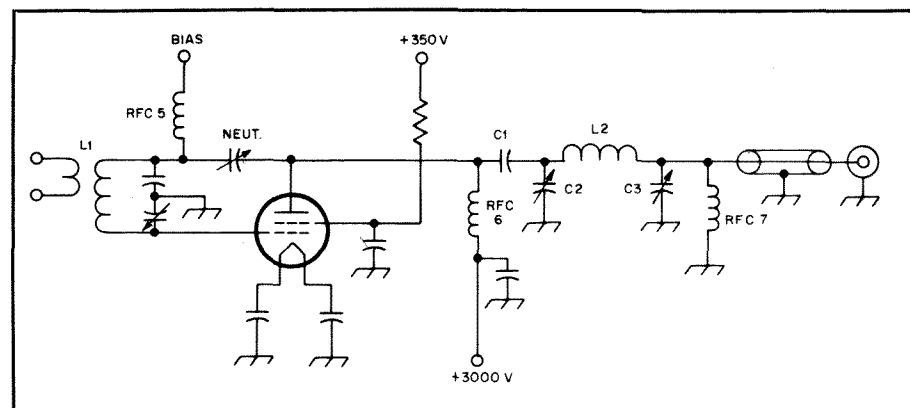

Fig. 82 — Transmitter applications for RF chokes vary markedly in regard to the quality of choke needed. In the grid circuit, RFC5 has no difficult job to do, and any choke suitable for low-power use is suitable. The shunt-feed choke, RFC6, must meet severe requirements, especially in high-powered amplifiers. It is effectively connected across the transmitter tank circuit, and is subjected to high temperature, current and voltage. The output choke, RFC7, is mainly a safety device, and it operates under much less stringent circumstances.

Teflon rod can be found in plastics supply houses, in  $\frac{1}{4}$ - and  $\frac{1}{2}$ -inch diameter. It drills and taps nicely, it won't melt, and its insulating quality is excellent. Bakelite rod or even wood dowelling is good enough for the less-critical choke applications. The smallest-diameter prepared coil stock is usable for 50-MHz chokes, but it won't stand much heat.

Space-winding RF chokes is easy. First drill through the rod at spacings indicated

under winding length in the table. Now measure off slightly more than a half wavelength of wire for the design frequency band. Double it back on itself and feed the end through one of the holes in the rod. Now wind the coil as if it were to be bifilar. If you clamp the other end of the double wire in a vise, or tie it down firmly otherwise, this can be done easily. Keep the wires under tension, and be sure they are not twisted at any point. Wind tightly and then

feed the end through the other rod hole.

Now remove one of the wires by unwinding carefully, keeping it under tension throughout. The remaining wire will be space-wound as neatly as if done by machine. Apply a thin coating of polystyrene cement, using a bit more around the lead holes, and your choke is done.

Self-supporting chokes of excellent quality can be made by winding no. 22 or 24 wire

tightly on various drill sizes, and then slipping the drill or other winding form out. If wound under tension the coil will hold its shape when slipped off the form. Turns can be spaced by running a thin knife blade between them.

You can tell a good choke from an inferior one easily enough. Connect it across your driver-stage tuned circuit, and see what it does to your final-stage grid cur-

rent. Also note how much you have to retune the driver circuit to restore resonance. A perfect choke would have no harmful effects, and it would not heat up. You won't find one that good, but a well-designed choke will come close. If the choke is not a good one, don't run the test too long at any appreciable power level, or you won't have to look for indications — you'll smell them!

## 6-Meter Amplifier Using the 3CX800A7

The amplifier described here uses the new EIMAC 3CX800A7 in a grounded-grid circuit. With 2200 V on the plate and 25-W drive, it will provide about 700-W output — enough for weak-signal work such as meteor scatter. The 3CX800A7 is well suited for this application. It combines low drive requirements normally associated with tetrodes, yet it offers the stability of grounded-grid triodes. Figs. 83 through 88 depict the amplifier. Dick Stevens, W1QWJ, designed and built this project.

### Circuit Details

Fig. 84 is a schematic diagram of the amplifier. The RF deck includes everything except the high-voltage power supply. Several suitable supplies are described elsewhere in this chapter and in Chapter 27. This amplifier requires 2000- to 2200-V at about half an ampere. The plate tank circuit is a pi-L network consisting of C11, C12, L3 and L4. This configuration gives somewhat better harmonic suppression than a standard pi network. The cathode input circuit is a T network consisting of L1, L2 and C8. A filament choke is recommended above 50 MHz to keep the filament above ground for RF. RFC2 is bifilar wound on a ferrite rod. According to sources at EIMAC, use of a center-tapped transformer at T1 is not necessary. If you have a transformer of the correct voltage, but without a center tap, go ahead and use it.

C13 and C14 bypass the B+ line. RFC3 is a hand-wound choke on a Teflon form, while RFC4 is an Ohmite Z-144. RFC5, an

Fig. 83 — The 3CX800A7 6-meter amplifier is mounted on a rack panel. Meters are mounted behind the panel with bezels.

Ohmite Z-50, is included for safety to prevent high voltage from appearing at the antenna connector if dc blocking capacitor C15 fails.

R1, in the B+ line, will protect the tube and power supply in case of a high-voltage arc. In this case, R1 was mounted in the power supply. It doesn't matter if you mount it in the power supply or the RF deck, but the use of this resistor is highly recommended.

Cathode bias is provided by a 5.1-V Zener diode, D5. R3 prevents the cathode voltage from soaring if D5 fails. F2 will blow if excessive cathode current is drawn. R4 nearly cuts the tube off on receive.

All metering is done in the negative

return lead for safety. C9, C10, D3 and D4 protect the meters. The antenna relay is located externally but is powered from the amplifier.

A grid overcurrent trip circuit is included to protect the 3CX800A7 from damage. The cost of the tube makes protection circuitry a must! Grid current is sensed across R5. If the grid current exceeds a preset value, Q1 conducts and actuates K1. Contact K1A, in the K2 coil supply line, opens and removes power from K2, placing the amplifier in STANDBY. To restore normal circuit operation, turn S2 to the off position; this will reset K1. S2 is "on" for normal operation. This switch provides an additional function: It controls the VOX

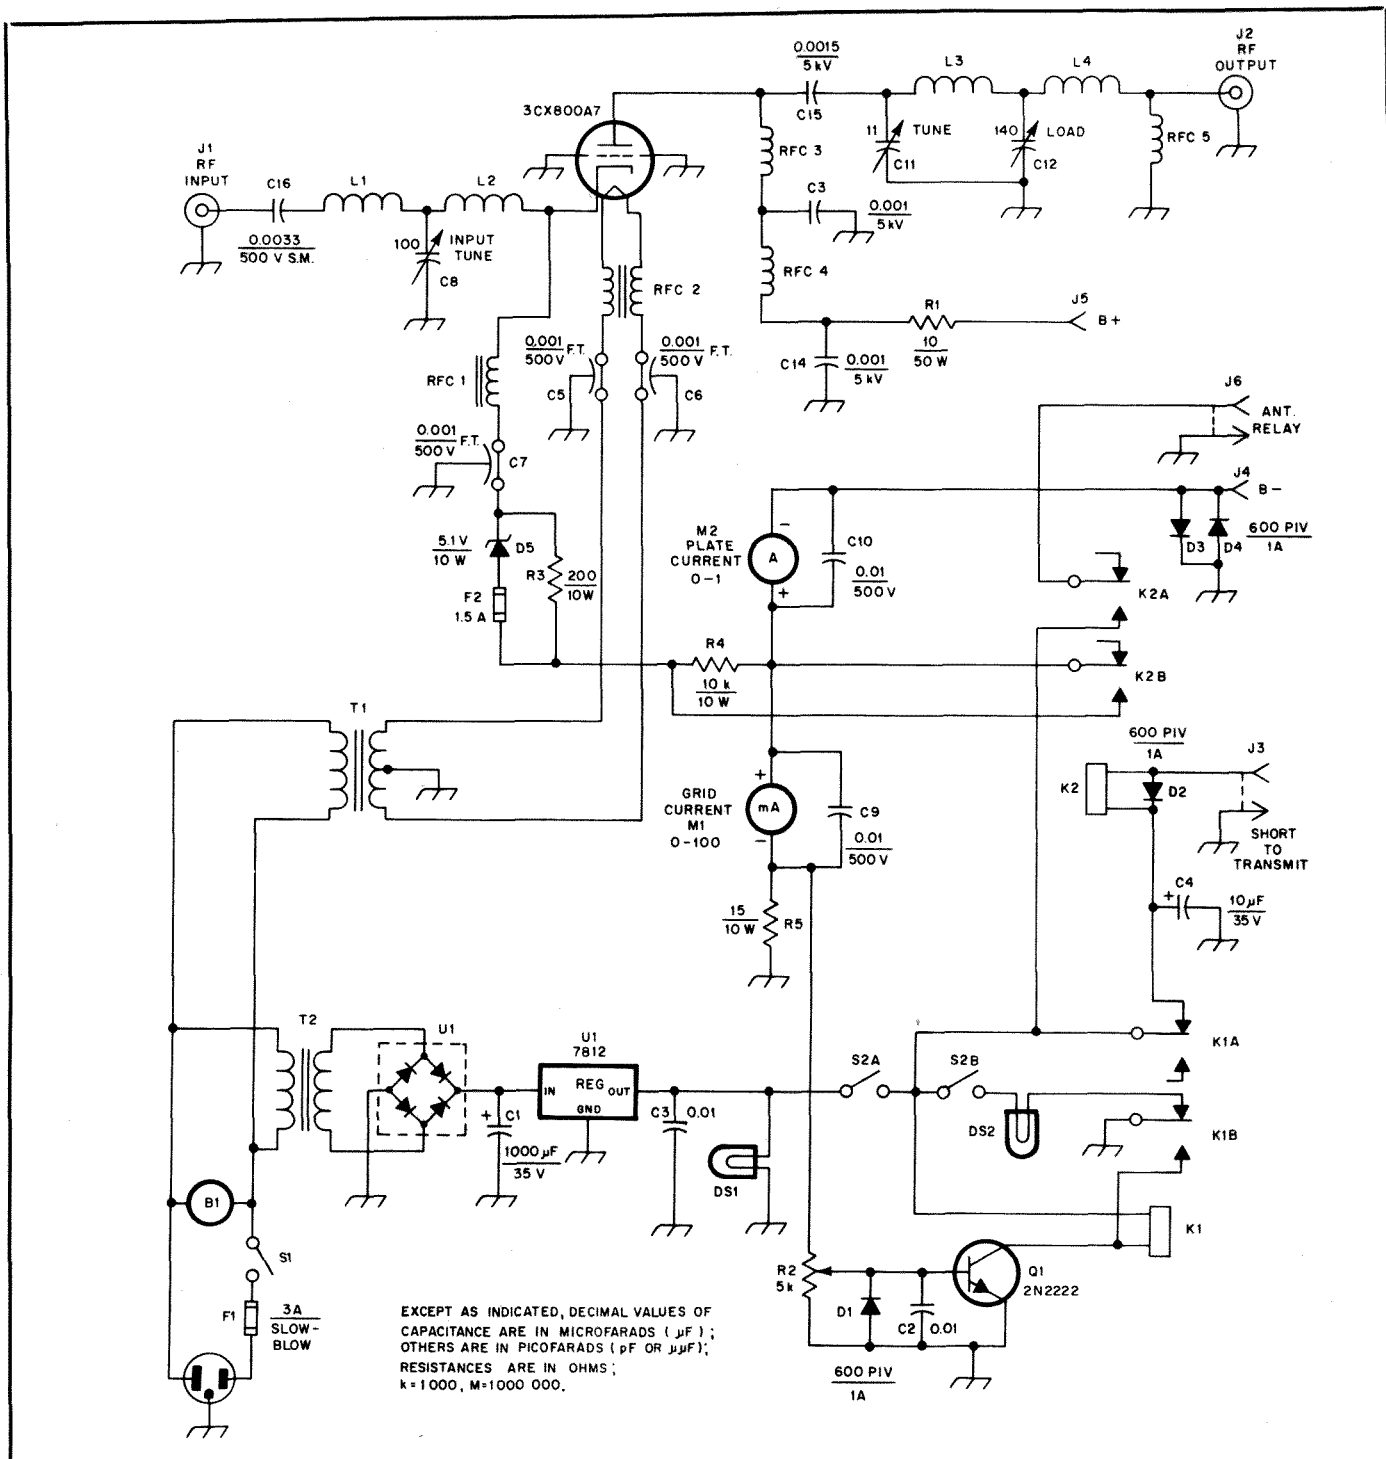

Fig. 84 — Schematic diagram of the 6-meter amplifier using the 3CX800A7. Resistors are  $\frac{1}{4}$ -W carbon types unless noted. Capacitors are disc ceramic types unless noted. SM means silver-mica. Capacitors marked with polarity are electrolytic.

B1 — Dayton 4C012A 54-CFM blower.

 U2 — 12-V, 1.5-A three-terminal regulator (LM7812 or equiv.).

circuit and antenna bypass relay circuit, so the amplifier can be switched in and out of the line between antenna and transceiver.

### Construction

The amplifier is built on a  $10 \times 12 \times 3$ -inch chassis (LMB 10123C). For the best possible RF shielding, the plate circuitry is built inside its own  $5 \times 10 \times 3$ -inch chassis (LMB 5103C) that is mounted on top of the main chassis. The chassis is attached to a standard  $19 \times 7$  inch aluminum rack panel (Hammond PBPA 19 007). The meters are mounted to the front panel with bezels.

Most of the parts used in this project were purchased from Radio Shack, Semiconductor Surplus, 2822 N. 32nd St., Phoenix, AZ 85008 and RadioKit, P.O. Box 411, Greenville, NH 03048.

Considerable care must be given to the tank circuit construction to keep stray capacitance to a minimum. To this end, the plate tuning capacitor (C11) is rebuilt from a receiving type. All available commercial capacitors had too high a minimum capacitance.

The first step in construction is to fabricate the plate tuning capacitor. The capacitor is made from a stock Cardwell ER25AS split-stator capacitor having a maximum capacitance of 25 pF per section, with four stator and five rotor plates. The capacitor is  $1\frac{5}{8}$  inches long between the end bearing plates and is made up of individual stator and rotor plates held together with spacers, washers and nuts.

Carefully disassemble the capacitor. Be careful not to lose any of the small parts. Two new no. 4-40 by 2- $\frac{1}{8}$ -inch-long tie rod bolts are needed. Reassemble the capacitor as a single section with four stator and three rotor plates with three spacers between plates. The completed capacitor will have a spacing adequate for 3.5-kV breakdown. The minimum capacitance is 4 pF and the maximum is 11 pF. Any capacitor of this type construction in the same general capacitance range should work. Alternatively, a small vacuum variable will work.

The tuning and loading capacitors, as well as L3 and C15, are mounted on an aluminum subassembly, as shown in Fig. 85. C12, the plate loading capacitor, is a standard value and required no modification. L3 is made of  $\frac{1}{8}$ -inch copper tubing and is suspended between C11 and C12. The bottom of L3 should be about  $\frac{1}{2}$  inch above the bottom of the subassembly. Additional details of the plate compartment may be seen in Fig. 86.

The subassembly is made from a piece of aluminum sheet that measures  $4\frac{3}{4} \times 5\frac{3}{4}$  inches. Fold up 2 inches on the longer side at a right angle to form an L bracket, as shown in Fig. 85. The capacitor shafts are mounted 1 inch in from each end, in the center of the 2-inch lip.

RFC3, the plate choke, is wound on a 2-inch length of  $\frac{3}{4}$ -inch-OD Teflon rod. Drill each end to a depth of  $\frac{1}{2}$  inch and

Fig. 85 — The output network mounts on a separate subassembly. C15 connects to the rest of the circuit with wide copper straps.

Fig. 86 — Top view of the 3CX800A7 6-meter amplifier with the plate-compartment cover removed. The blower pressurizes the plate compartment and air exhausts through a chimney made from Teflon sheet (not shown). A Dow-Key 260B is used here as a TR relay. T1 and K2 are mounted on top of the chassis.

tap for no. 10-32 hardware. Screw a 1-inch length of no. 10-32 threaded rod (or a bolt with the head cut off) into each end. Starting at  $\frac{1}{2}$  inch from one end of the rod, wind 40 turns of no. 22 enameled wire. Leave extra wire at each end for making connections. The winding should be about 1 inch long and is centered on the form.

Secure both ends of the winding with epoxy cement. Slip a no. 10 solder lug over one of the pieces of threaded rod and solder one end of the winding to it. This will be the end that attaches to C15.

The plate compartment is pressurized, and a chimney made from Teflon sheet that fits around the tube anode forces the air

Fig. 87 — The underside of the chassis is divided in half by a partition to shield the input circuit.

**Table 4**

**Typical Operating Conditions for the 3CX800A7 6-Meter Amplifier**

Plate supply voltage	2200 V
Zero-signal plate current	65 mA
Single-tone plate current	500 mA
Single-tone grid current	40 mA
Drive power	25 W
Output power	700 W
Efficiency	62%

up through the tube to an exhaust hole cut in the top of the plate compartment. The hole is shielded with aluminum screen. Details of this type of chimney and cooling system may be found in the 2-meter 8930 amplifier project presented later in this chapter.

Fig. 87 shows the underside of the amplifier chassis. A partition down the center of the chassis shields the input circuitry. The tube socket, input network and filament choke mount on one side of the partition. The dc components and control circuitry mount on the other. Operating voltages reach the tube through feedthrough capacitors in the partition.

To insure stability, the grid grounding straps should go from pin 4 to pin 7, and from pin 4 to pin 11. Ground pin 4 to the chassis at a solder lug at one of the tube-socket mounting screws. These pin numbers are for the EIMAC SK-1900 socket. Alternatively, EIMAC can supply a collet (part no. 720359) to ground the grid. The cathode straps should go between pins 1-8, 2-9 and 3-10. Solder these straps

together where they cross at the center of the socket and make the cathode RF connection to this point.

Filament choke RFC2 is wound on a ferrite core. Cut two 36-inch lengths of no. 16 enameled wire and bifilar wind them on a ½-inch wooden dowel. Dress the ends to make the winding 2 inches long. Cut a 3-inch length of ferrite rod and file the ends so there are no sharp edges. Carefully slide the bifilar winding off the dowel and onto the ferrite rod. After the winding is centered on the rod, give it a coat of epoxy cement to hold it in place. See Chapter 24 for more details on this type of RF choke.

The grid protection circuitry is built on a small piece of Radio Shack part no. 276-159 prototyping board. One half the board is used. Most of the other components mount to the chassis or to terminal strips.

#### Initial Tune-Up and Adjustment

Connect an SWR meter between a 6-meter transmitter capable of supplying 20 W and the amplifier input. Connect a wattmeter and a good 50-ohm dummy load capable of handling at least 700 W to the output connector. Close S1 and allow the 3CX800A7 to warm up for at least 3 minutes before applying plate voltage. Caution: never apply filament voltage without the blower running. Never apply drive without plate voltage and a load connected to the tube, or the tube grid-dissipation rating may be exceeded.

Apply low plate voltage, about 1 kV, and apply a watt or two of drive. Adjust C8 for

Fig. 88 — Spectral output of the 3CX800A7 6-meter amplifier. Power output is 700 W on 50 MHz. Each vertical division is 10 dB and each horizontal division is 10 MHz. All harmonics and spurious emissions are greater than 64 dB down. This amplifier complies with current FCC spectral purity requirements.

minimum input SWR. It might be necessary to spread or squeeze turns on L2 to get a 1.1:1 SWR.

Adjust C11 and C12 for maximum output. There is not much leeway with L3. It has to be the correct value to resonate with the output capacitance of the 3CX800A7 and the low capacitance of C11. Chances are that you may have to shut the amplifier off, disconnect the high voltage and spread the turns on L3 slightly to get the output circuit to resonate properly. The circuit should resonate with C11 set at ½ mesh.

When you get the output circuit to resonate at low power, bolt down all the covers and apply full plate voltage. Zero-signal plate current should be 65 to 70 ma. Apply a couple of watts drive and tune the amplifier for maximum output. Slowly increase the drive, keeping the output tuned for maximum. With 10-W drive from a typical multi-mode transceiver, output should be 400 to 500 W. With 25-W drive, output should be approximately 700 W. Table 4 lists typical operating conditions. Check the input SWR at full power and re-adjust as necessary.

Most likely the grid overcurrent trip circuit will operate at some point during the initial tune-up, placing the amplifier in STANDBY. Decrease the sensitivity by adjusting R2, mounted on the grid-trip circuit board. A hole is cut in the chassis bottom plate for access to this control. With the values shown, the circuit should trip at 20 mA with R2 set to a minimum. Adjust R2 slightly until the circuit holds at 40 to 50 mA of grid current. The tube's maximum grid-current rating is 60 mA.

A spectral photograph of the amplifier output is shown in Fig. 88. It meets current FCC spectral-purity requirements.

# A 2-kW PEP Amplifier for 50 to 54 MHz

A number of manufacturers sell low-power-output (10-watt) transceivers and transverters for 6-meter operation. This particular power-output level is not in line with that required to drive the popular grounded-grid amplifiers. Even the high-mu triodes, such as those of the 8874 family, require at least 25 watts of drive for 1 kilowatt of input. Over 50 watts of drive may be required for 2-kilowatt service.

This leaves two options for owners of 10-watt-output rigs. One solution is to use a solid-state "brick" amplifier to drive the grounded-grid amplifier. This results in complex relay-switching systems not to mention the cost of the amplifier and a high-current supply to power it. The other approach is to use a tetrode such as the 4CX1000A in a grounded-cathode amplifier (see Figs. 89 through 97). In this circuit, 10 watts of drive will provide 2 kilowatts of input power, thereby eliminating an intermediate amplifier stage.

## Circuit Description

The schematic diagram of the amplifier is shown in Fig. 90. As the 4CX1000A is a high-mu tube, care must be taken in the design and construction of the amplifier to prevent instability. In the circuit shown, this was accomplished without the need for neutralization — one of the drawbacks commonly associated with the use of these tubes.

The input network is series tuned. A link couples power from the exciter to the tube. Series tuning was chosen primarily because of the large input capacitance of the tube (roughly 100 pF). The tube socket and strays add an additional 20 pF. This tuning method places the tube input capacitance in series with the tuning capacitor, effectively reducing the tuning capacitance. A number of other networks were tried, including one somewhat exotic current-feed method, but none proved as simple and effective as the one shown. Bias voltage is shunt fed to the grid through R1. This resistor also heavily swamps the grid circuit and helps to provide amplifier stability without the need for neutralization. Should it be desired to increase the gain of the amplifier for use with lower power rigs, the value of R1 can be increased and the network components changed as appropriate. The cathode is grounded through short, heavy leads at the base of the SK-800B tube socket. A screen bypass capacitor is an integral part of this socket. The capacitor is 1500 pF, is rated for 400 volts and is of the mylar-film variety. Capacitors are connected between ground and each of the three filament-connection points.

The plate circuit used in this amplifier is of the common pi-network variety, with two exceptions. First, the internal tube plate capacitance, which is on the order of

10 pF, comprises what would be considered the "tuning" capacitor of the network. Since the tube capacitance is fixed, the inductor is used as an adjustable element. A compressible/expandable coil is used here. This arrangement allows the amplifier to cover the entire 6-meter band, whereas other designs using shorted-turn and slug-tuned techniques will cover little more than 1 MHz of tuning range. Additionally, the compressing and expanding of the coil does not have an adverse effect on the inductor Q, as typically occurs with the other systems. The tube capacitance dictates the circuit Q, which is roughly 14.

A single, multisecondary transformer provides power for the filament, bias and screen supplies. Although the filament winding is rated for 6.3 V at 8.8 A, the transformer delivers 6.0 V at 9.0 A — precisely that required by the 4CX1000A. The transformer was run for a period of 10 hours under these conditions and no appreciable heating of the wires or core was noted. Transformers of other manufacture or different voltage/current ratings should be carefully checked.

The high-voltage secondary of the transformer provides energy for the bias and screen supplies. Zener diodes limit the dissipation of the bias potentiometer. R6 cuts the amplifier off during receive periods. J5 is shorted for transmit.

The transformer secondary also feeds the screen supply. Here, a full-wave rectifier provides the dc energy. Q1, D3, R1 and R2 form a regulator that limits the current that can be drawn through the transistor to 40 mA. This extra circuitry is desirable in the event of high-voltage supply failure. No more than 40 mA of current can be drawn through the regulator, ensuring that the screen is protected. Without such a safety device, a failure of the high-voltage supply would mean that the screen dissipation might be pushed well above the specified 12-watt maximum rating. D4-D9, inclusive, make up the screen-voltage regulator.

M1, located in the -HV lead, continuously monitors cathode current. Meter shunts are provided in the bias and screen supplies. M2 can be switched between grid and screen by means of S2. This meter reads 0 to 10 mA for grid and 0 to 100 mA for screen current.

The amplifier requires a high-voltage supply. The design and construction of such supplies is covered in Chapter 27.

## Construction

Many of the construction details can be seen in Fig. 91. The general layout is not especially critical, although good isolation between the grid and plate circuitry is a must. To this end, the Eimac SK-800B socket is used. The built-in screen-bypass capacitor is an important factor in amplifier stability. Other sockets without this

Fig. 89 — Front-panel view of the 2-kW, 6-meter amplifier.

capacitor should be avoided.

The amplifier is built on a 10 × 12 × 3-inch aluminum chassis that is attached to an 8 3/4 inch-high, 19-inch-wide rack panel. Sheet-aluminum panels are made so that the overall height of the amplifier enclosure is 7 1/2 inches.

The grid compartment is constructed from a second aluminum chassis that measures 7 × 7 × 2 inches. It is easiest to cut the hole for the tube socket with the smaller chassis bolted in place. In this manner exact alignment can be guaranteed. A heavy-duty hand nibbler tool was used to make the large hole. All leads entering the grid compartment pass through 1000-pF feedthrough capacitors to ensure an RF-tight enclosure. The amplifier input connection is through a UG-625B (female) chassis-mount BNC connector, directly into the grid compartment. The general placement of the input-network components can be seen in the photograph. A perforated aluminum cover is placed over the smaller grid-compartment chassis. This piece must allow adequate air flow for proper tube cooling. It is a good idea to check air flow with and without this piece in place in order to determine whether the material is suitable.

The remainder of the bottom chassis houses the screen and bias power-supply components and the control circuitry. Many of the parts are contained on a single-sided circuit board. The parts-layout diagram is shown in Fig. 96. Zener diodes are mounted on an aluminum plate and the circuit board. While the aluminum provides some heat-sinking, cooling for the diodes is supplied primarily by the system blower, as the diode stack is mounted in the air flow path. Cooling for the tube is by means of a blower that is mounted external to the chassis. A plastic flange (Newtone 366, used with central vacuum cleaning systems) is suitable for use with 2-inch automobile heater/defroster hose. A length of this hose connects the pressurized chassis to the blower, which can be mounted at some convenient location. For ultra-quiet operation the blower can be mounted in a closet or in an adjoining room. Copper or brass screening is used to cover the flange opening, thus maintaining an RF-tight chassis. Information on how to select a

suitable blower is given in Chapter 15 of this *Handbook*. Connection to the meters is through 1000-pF feedthrough capacitors.

The plate compartment is somewhat less busy than the underside of the amplifier. See Fig. 92. The only component that needs explanation is the inductor. Details of the construction are shown in Fig. 93, and a photograph is shown in Fig. 94. Two pieces of 3/8-inch Delrin plate are used as the stationary end pieces. A 1/4-inch control bushing is used at the center of each piece. A third piece of Delrin stock is used for the movable plate. This piece is tapped to accommodate the 1/4-28 thread of the shaft that is used to move the plate. This shaft

Fig. 93 — Dimensional drawing of the inductor assembly. Delrin can be obtained from most plastic supply houses. Check the Yellow Pages of your local telephone directory for dealers.

Fig. 94 — Photograph of the assembled adjustable inductor. Make certain to use only plated brass hardware for pieces that come into contact with the coil.

is double nutted on each side of the rear support to prevent the shaft from moving in relation to either the front or rear supports. As the front-panel knob is turned, only the movable plate changes position to compress or expand the coil. The exact dimension of the coil is fairly critical, so it should be made as close to specification as possible. Once the coil has been wound it can be silver plated to prevent oxidation.

As a point of interest, the amplifier front panel was painted orange. Black press-on lettering was used to label the front panel controls. A light coat of clear lacquer was applied to protect the lettering.

#### Operation

It is a good idea initially to check out the various tube-element voltages without the tube in the socket. The screen voltage may

Fig. 95 — Photo (A) and schematic diagram (B) of the low-pass filter that is used after the amplifier. The filter is built to fit inside a 2 1/4 x 2 1/4 x 5-in box. Good quality capacitors such as silver-mica types should be used.

L2 — 5 turns no. 14 wire, 7/16-inch ID.

turn out to be different than the nominal 336 because of poor Zener-diode voltage tolerances. As long as the voltage is under 375 no problems should be encountered. Operation of the protective circuitry can be verified by loading the output of the screen supply with appropriate high-wattage resistors. Ensure that the bias control will allow adjustment between the values shown on the schematic. Set the voltage to roughly -150 so that the tube will be cut off when

Fig. 96 — Parts-placement guide for the printed-circuit board as shown from the component side. A full-size etching pattern can be found at the back of this book.

the amplifier is first turned on. Eimac recommends that the 4CX1000A heater voltage be applied for a period of not less than three minutes before plate voltage and current are applied.

Connect a transmitter capable of supplying 10 watts of power to J1 through an SWR indicator. Also, connect a dummy load and power meter to J2. After the amplifier has warmed up for several minutes, short J5 and adjust the bias control for an idling current of 50 mA. Apply a small amount of drive power and adjust L3 and C6 for maximum power output. Next, adjust C1 for minimum reflected power as indicated by the input SWR indicator. Apply additional drive power and

continue adjusting L3 and C6 for maximum power output. Use the operating parameters given in Table 5 as a guide. For the amplifier described here an adjustable high-voltage supply was used. The voltage and current levels for 1-kW and 2-kW input level were chosen to equalize the plate impedance, thus requiring only a minimal change in the settings of L3 and C6 for changing power level. If the fixed-voltage supply is used to power this amplifier, similar efficiencies should be attained.

As with many amplifier designs for VHF operation, additional low-pass filtering is required to meet the FCC spectral-purity requirements (all spurious and harmonic emissions – 60 dB or greater below peak

Table 5  
Operating Parameters

	1 kW	2 kW

power). A suitable filter circuit is shown in Fig. 95. The unit was constructed in a small aluminum box and is mounted directly at the output connector by means of a double-male adapter. With this filter the amplifier easily exceeds the FCC requirements. A spectral photograph is shown in Fig. 97.

# A Medium-Power 144-MHz Amplifier

The typical 2-meter rig these days puts out 10 watts or so. While 10 W is adequate for local communications, it is not enough for reliable long-haul work. Although occasional band openings and enhanced conditions allow long-distance contacts with low power, something more is desirable for weak-signal work. The amplifier pictured in Figs. 98 through 110 will supply more than 300-W output for 10-W of drive. It is clean, easy to build and reliable. If the builder shops wisely, the entire amplifier can be built for less than the cost of a commercially manufactured 150-W "brick" amplifier and associated 20-A, 13.8-V regulated supply. This project was designed by Clarke Greene, K1JX, and built by Mark Wilson, AA2Z, in the ARRL lab.

## Circuit Details

An 8930 tetrode (350-W plate dissipation) is used in this design. The 8930 is identical electrically to the 4CX250R, but it features a larger anode cooler for higher dissipation with lower air flow and pressure drop requirements. If the builder must purchase a new tube, the 8930 is a good choice because it is more rugged than the 4CX250. However, a commonly available 4CX250B will work fine in this circuit. Only minor mechanical changes are necessary to accommodate the 4CX250's smaller anode cooler. The amplifier and power supply are shown schematically in Figs. 99 and 100.

The input circuit consists of L2, which is series tuned by C2 and the tube input capacitance. C3 is used in parallel with C2 to preset the tuning range for a smooth vernier action. A single 15- or 20-pF variable may be used at C2, but the tuning will be more critical. Power is coupled to L2 through link L1.

Bias voltage is fed to the tube through R1. This resistor, which consists of three 820-ohm, 2-W carbon composition resistors in parallel, swamps the grid heavily. Heavy swamping is important for amplifier stability. It also raises the drive requirement to about 8 W for full output. The amplifier can be driven to full output with about 2 W if the grid swamping resistor is changed to 2000 ohms or so and the input matching is adjusted accordingly. Excessive drive, however, will make the tube run in the nonlinear region, causing splatter up and down the band. It is impossible to adequately control the drive power by adjusting the exciter mic gain control. An input circuit designed for the drive level available from the exciter makes it difficult to overdrive the amplifier, ensuring a clean signal and peaceful co-existence with nearby amateurs sharing the band.

The output circuitry consists of a quarter-wavelength strip line, L3, which is tuned by C9. A tuned link, L4 and C10, couples power to the output jack. High

Fig. 98 — The 8930 amplifier and accompanying high-voltage power supply are built behind standard 19-in rack panels.

voltage is fed to the tube at the low-impedance (ground) end of the line through RFC1. C8 is the plate-blocking capacitor.

The filament, bias and screen voltages are all supplied by T1. EIMAC specifies filament voltage at  $6.0 \pm 0.3$  V, so R11 is included to drop the transformer voltage to the proper level.

T1 has a secondary winding of 270-0-270 V which is used for the screen and bias supplies. Screen voltage regulation is accomplished by five 60-V Zener diodes, D7 through D11. The voltage from the supply is dropped to the Zener stack voltage by current-limiting resistor R5. R7, a screen bleeder resistor, is connected in parallel with the Zener stack to allow for negative screen current developed under certain tube operating conditions.

A tetrode should not be operated without plate voltage and a load. Otherwise, the screen would act like the anode and draw excessive current. Should this happen accidentally, F2 will blow and protect the screen. F2 is placed between the Zener stack and the bleeder, rather than between the bleeder and the tube. If the tube were operated without a load on the screen, the screen potential would rise to the anode voltage, destroying the screen bypass capacitor. Should the screen voltage rise above 390 V, Z1, a metal-oxide varistor, will conduct and clamp the screen voltage to ground. The power-supply fuse should blow before any damage occurs.

Bias voltage is taken from the same secondary winding as the screen voltage. When the amplifier is in standby, -200 V is applied to the grid to cut the tube off. In transmit, D12 is switched in, supplying operating bias. R9 is used to adjust operating bias from -40 to -60 V to allow for differences among tubes. D15 is included to minimize Zener voltage drift as D14 changes temperature.

The 5-V winding on T1 supplies coil voltage for K1. Contacts K1B switch the bias from standby to operate. K1C provides "dry" contacts for antenna relay switching.

S1 applies voltage to the blower motor, while S2 energizes T1. These two switches are connected so that the blower must be

switched on before filament voltage is applied. The blower may be left on after the amplifier has been turned off.

The high-voltage supply is designed to deliver 2000 V under load. The heart of the supply is a heavy-duty Hammond transformer that will run cool even under continuous use. The 234-V primary and full-wave bridge rectifier in the secondary aid voltage regulation.

The B+ supply is turned on from the amplifier front panel, so the supply may be located away from the operating position. K1 is a heavy-duty power relay with contacts large enough to handle the supply current. R1 and R2 provide inrush current protection for the rectifiers. These resistors are shorted out by the contacts of K2, applying full primary voltage after a short delay. This delay is about 0.6 second, and is determined by R3 and C1.

D1 through D4 are high-voltage rectifiers provided by K2AW. They eliminate the need for a PC board full of individual 1000-PIV units with associated capacitors and equalizing resistors. C2 is a surplus oil-filled capacitor. Individual electrolytic capacitors would work fine, if enough units are connected in series to give about 40  $\mu$ F at a voltage rating of at least 2500 V.

R4 through R6 make up the bleeder resistor. Several individual resistors are used, rather than one large unit, to keep the voltage across each resistor within ratings. F2 is a high-voltage fuse that will protect the power supply and amplifier in case of a short circuit. The negative lead of the power supply floats above chassis ground so that plate current may be monitored in the negative lead in the RF deck. R8 keeps the B- lead close to chassis potential. R9, in series with the B+ lead, protects the tube and power supply from high-voltage flashovers.

Plate current is monitored by a 0- to 500-mA meter in the negative lead. A 0- to 5-mA meter monitors grid current and screen current. Shunt R6 increases the movement to a 50-mA range for the screen. The high-voltage supply has a separate 0- to 4-kV meter.

supply from the RF deck, is wired so it is impossible to key the amplifier until the B+ is applied. When S2 is thrown, the filaments, bias and screen supplies all come on together. If operating bias was placed on the tube (by keying the amplifier) and no B+ was present, the screen would draw excessive current, as described before. As long as the tube is cut off, having screen voltage present without plate voltage is not a problem.

### Construction

The 8930 amplifier is built using three separate chassis (see Figs. 101 and 102). The main chassis measures 10 × 17 × 3-in and is bolted to a standard 19-in-wide, 8¾-in-high rack panel. The plate compartment is a 13 × 5 × 3-in chassis, while the input compartment is a 4 × 5 × 2-in chassis. Use of separate enclosures ensures good shielding.

Amplifier cooling is accomplished using a split airflow, rather than the conventional base-to-anode flow. The blower pressurizes the plate compartment. A special chimney, fabricated from Teflon sheet and phenolic tubing (see Fig. 105), seals the area between the tube cooler and the plate compartment top cover. Air enters the plate compartment and exits through the anode cooler. Some of the air exits through the tube socket to cool the tube seals and input compartment. Measurements by ARRL TA Dick Jansson, WD4FAB, indicate that this cooling system reduces blower back-pressure requirements by about 50 percent with this tube. The blower chosen is capable of supplying 25 cubic feet per minute at 0.4-in of static column pressure — more than enough to cool the amplifier, even at full dissipation.

An EIMAC SK-620A socket is used in this project. The SK-620A and SK-630A sockets feature built-in low-inductance screen bypass capacitors and screen

Fig. 101 — Top view of the 8930 2-m amplifier. The tube and plate circuitry are mounted in a separate chassis that bolts to the main chassis. The plate compartment top cover has been removed for clarity, although it must be installed during amplifier operation.

shielding rings. These features are essential to amplifier stability. If possible, an SK-630A should be used because it features grounded cathode pins. The SK-620A was used here because one was on hand. The four cathode pins are bent in toward the socket center ring and soldered to it, assuring a solid, low-inductance cathode ground.

The input compartment is centered on the tube socket. Filament, bias and screen voltages enter the input box through feedthrough capacitors. All leads are kept as short as possible. The swamping resistor is connected between the feedthrough capacitor and the grid terminal. Likewise, the 100-ohm screen isolation resistor connects the screen pin and the feedthrough capacitor. L2 is supported by C2 and the

socket grid pin. L1 is mounted on a small ceramic standoff insulator near L2. J1 is a panel-mount BNC connector attached to the rear panel and connected to L1 by a short length of 50-ohm coaxial cable.

The plate compartment is mounted along the rear of the main chassis. Fig. 103 shows the relationships of the pieces inside the compartment. Details of L3, L4, C8 and C9 are given in Fig. 104.

L3 is a ¼-wavelength strip line made from brass and aluminum sheet. Complete details are shown in Fig. 104. One end bolts to the chassis, while the other end is silver-soldered to a copper strap that clamps around the anode cooler. C8, the plate blocking capacitor, is a "sandwich" capacitor formed by the two pieces of the plate line. The dielectric is a piece of 0.01-in

Fig. 102 — Underside of the 8930 2-m amplifier. The input circuitry is enclosed in a separate chassis. The screen and bias supplies are built on small printed-circuit boards. D7-D11, the screen regulator Zener diodes, are mounted on a piece of 1/4-in-thick aluminum plate for adequate heat-sinking.

Fig. 103 — Component mounting information for the plate compartment.

thick Teflon sheet. Three 6-32 brass screws hold the sandwich together. The top half of the line has B+ on it, and the bottom half is grounded, so Teflon shoulder washers are used to insulate the screws from the top half of the line. The shoulder washers used here were cut on a lathe from 3/4-in-diameter Teflon rod. A light coating of Dow Corning DC-4 silicone grease is spread on each side of the Teflon sheet to fill in any irregularities.

In this amplifier, the bottom half of the

plate line is formed from a single piece of aluminum sheet bent in a sheet metal brake. With patience and a good bench vise and hammer, it should be possible to get a clean bend. If the builder does not have sheet metal bending capability, the bottom half of the line may be made from two separate pieces bolted together. The plate line may be made from copper or brass if this method is used. The top half of the sandwich must be made from copper or brass because it is soldered to the tube clamp.

C9 is made from two brass plates. Fig. 104 gives complete mechanical details of the capacitor assembly. One plate is silver soldered to the anode clamp. The movable plate is attached to a 1/4-in Delrin rod supported by bushings in the chassis walls. A wide, low-inductance strap made from 0.003-in thick brass shim stock connects the movable capacitor plate to the chassis. A length of 1/4-in-square brass bar is drilled and tapped to hold the shim stock securely against the chassis. A Jackson 6:1 ball drive (available from RadioKit — see Chapter 35 parts suppliers list) is used on the capacitor support shaft to ensure smooth tuning. A 6-32 machine screw tapped into the Delrin shaft ensures a solid mechanical stop. The two capacitor plates must *not* be allowed to touch — one plate is at ground potential, while the other is at 2 kV.

The copper, brass, Teflon, Delrin and aluminum stock necessary for this project are available from Small Parts, Inc. (see Chapter 35 parts suppliers list). Brass or plated brass hardware should be used throughout the plate compartment. Steel is unacceptable for use in strong RF fields. After assembly, the anode clamp, C9 plates and brass half of the plate line were treated with rub-on silver plating.

L4 is made from a piece of no. 14 tinned wire suspended over the cold end of the plate line. Details are shown in Fig. 104. It is supported on the ends by J2 and C10. Greatest coupling occurs when the section of the link that runs parallel to the strip line is placed over the center of the line. In this amplifier, best coupling occurred with the link spaced about 1/4-in above the line, but the builder should experiment with different spacings to find the optimum distance for best efficiency.

High-voltage enters the plate compartment through feedthrough C6. RFC1 is soldered between C6 and the cold end of the line. Carefully clean away all flux from the plate line after soldering. Any flux left near the end of the line may offer a path for a high-voltage arc across the sandwich capacitor.

Brass screen, soldered to a brass plate, covers the blower inlet to ensure good shielding. Similarly, a piece of screen soldered to a plate shields the hot air exhaust. A liberal number of machine screws are used to secure the plate compartment top cover to the chassis to keep the RF in. The machine screws thread into aluminum captive fasteners pressed into the chassis. These fasteners are available from Penn Engineering and Mfg. Co., Danboro, PA 18916.

All parts for the screen and bias supplies except D7 through D11 and their 0.01-μF bypass capacitors are mounted on printed-circuit boards. Parts layouts for these boards are given in Fig. 106, and full-size etching patterns are given at the back of this book. The resistors tend to run warm, so they are spaced about 1/4-in off the board to allow airflow on all sides. D7

Plate current (idling)	90 mA
Screen current	15 mA
Power input	580 W
Power output	340 W
Efficiency	59%
Drive power	6 W

8½-in-high rack panel (see Fig. 107). The major power supply components are bolted to a 1/8-in-thick plate. The front, rear and side panels are attached to the bottom plate by pieces of aluminum angle stock. All connections are made via the rear panel. Only the high-voltage meter (to show that the secondary is on) and a pilot lamp (to show that primary energy is applied) are mounted on the front panel. The high-voltage projects in Chapter 27 show full details on this type of construction.

#### Tune Up and Operation

When the wiring is complete, check and recheck all connections. The voltages present in this amplifier are potentially dangerous. Disconnect the filament, bias and screen supplies at the feedthrough capacitors on the input compartment. Turn on T1, if possible through a variable autotransformer, and check the voltages. The filament should be about 6-V ac. The screen supply should be around 300 V, plus

through D11 are mounted with insulating hardware on a ¼-in-thick aluminum plate that is bolted to the chassis for heat sinking.

M1 and M2 are Simpson Model 1327 3½-in meters. They are mounted behind the front panel using Simpson mounting bezels and illumination kits. Larson Instruments designed custom meter scales drawn for this project. M2 has two scales;

the GRID CURRENT scale reads 0 to 5 mA, while the SCREEN CURRENT scale reads — 10 0 10 20 30 40 mA. The screen supply bleeder resistor draws 10 mA, so the zero for the SCREEN scale is offset 10 mA. Ordering information for these meters is included in the parts list in Fig. 99.

The high-voltage supply is built on a separate chassis, also mounted behind an

(A)

(B)

Fig. 108 — Spectral photograph of the 8930 2-meter amplifier is given at A. Power output is 340 W. Horizontal divisions are each 10 MHz; vertical divisions are each 10 dB. A shorted  $\frac{1}{4}$ -wavelength stub (Fig. 109) is necessary to make the amplifier meet current FCC spectral-purity requirements. The spectral photograph at B, taken with the stub installed, shows that all spurious and harmonic emissions are at least 60 dB down. In both photos, the fundamental has been reduced in amplitude by 30 dB by means of notch filters to prevent analyzer overload.

nect the output directly to a dummy load.

Start the blower and check for airflow. Turn on T1, again preferably through a variable autotransformer in case of trouble. The exhaust air should be slightly warm from the filament. The screen current meter should read 0 (10 mA upscale from the current drawn by R7). The plate and grid current meters should not move.

After a minute or so, gradually apply plate voltage. Bring the voltage up to 1000 V or so. Listen and watch for any signs of high-voltage arcing. If everything seems okay, key the amplifier at J6. Adjust the idling plate current to approximately 90 mA using R9. Screen and grid current should stay at zero.

Apply a few watts of drive and adjust C2 for minimum reflected power on the SWR meter connected to the input. If the SWR is not better than 1.2 or 1.3, shut off the amplifier. Disconnect the high voltage, open up the input compartment and adjust the position of the link. It may take several tries, but it is important that the input match be as good as possible for best IMD characteristics. If moving the link does not bring the input SWR close to 1.2, try adjusting the spacing of L2 slightly.

When the input is matched, turn on the amplifier and bring the plate voltage up to 2000 V. If no arcing is noticed, apply a small amount of drive and tune C9 and C10 for maximum output. Increase drive slowly, and readjust C9 and C10 for maximum output. Watch the screen and plate current, and do not exceed the manufacturer's ratings. Table 6 lists the normal operating parameters for this amplifier. Six watts of drive should produce about 340-W output. If the efficiency is very much different from that shown in the table, try adjusting the position of the link with respect to the plate line.

This amplifier is extremely stable. With operating voltages applied (and no drive), the controls were tuned through their ranges with no hint of instability. This amplifier is not neutralized, so maximum output may not occur with the plate dip. The grid, tuning and loading controls work smoothly. Their adjustment is not critical — in fact, tuning is smoother than on some commercially manufactured HF amplifiers.

Spectral photographs are shown in Figs. 108 and 110. In Fig. 108A the second and fourth harmonics are about 50 dB below the amplitude of the fundamental. The sixth is 58 dB down. By increasing the value of C10 and reducing the size of L4, it is possible to raise the link Q to the point where the amplifier meets FCC spectral-purity requirements (all spurious and harmonic emissions at least 60 dB down); however, the high-Q link makes retuning necessary for small excursions in the 2-meter band.

Addition of a simple shorted stub cut to an electrical quarter wavelength at 144 MHz (Fig. 109) results in the spectral

Fig. 109 — Details of the  $\frac{1}{4}$ -wavelength stub.

Fig. 110 — Two-tone spectral photograph of the 8930 2-meter amplifier. Power output is 340 W PEP.

or minus a few volts. This may change some as the Zeners heat up to their operating temperature. The bias voltage should be about -200 V. Close the TR relay, K1. Bias voltage should change to somewhere around -50 V. If everything checks out, unkey K1 and turn the power off.

Connect the filament voltage to the feedthrough capacitor on the input box. Turn on the blower and check for airflow. Turn on T1 (remember, no voltages other than filament are applied to the tube). Use an accurate voltmeter to check the voltage at the socket filament pins. Adjust R11 until the filament voltage is exactly 6.0 volts. Turn off the filament voltage and blower, and connect the screen and bias supplies to the appropriate feedthrough capacitors. Put the cover on the input compartment.

Connect the high-voltage supply to the RF deck. Connect a dummy load to J2 through an accurate VHF wattmeter, such as a Bird Model 43. Connect a 2-meter rig capable of supplying about 10 W to J1 through another VHF wattmeter. If only one wattmeter is available, connect it to the input first for initial adjustments and con-

nect the output directly to a dummy load. At the transmitter end, the stub looks like an open circuit for RF at 144 MHz, but it looks like an RF short circuit at the even harmonics. The only visible harmonic energy is at the fourth, and this is just out of the analyzer noise floor at -62 dB.

The shorted stub serves a second purpose as well. In the unlikely event that the link detaches from its mounting and falls on the top of the plate line, placing high voltage on the output connector, the stub will short the dc to ground and blow the power supply fuse.

A two-tone test of this amplifier is shown in Fig. 110. The test setup consisted of two RF tones, one at 144.200 MHz and the other at 144.201 MHz fed into a combiner and then into the amplifier input. Except for the third-order products, which are down 28 dB from PEP, all IMD products generated within the amplifier are lower in amplitude than those found in most 10-W, solid-state, 2-m transceivers.

# A 144-MHz Amplifier Using the 3CX800A7

The amplifier described here and pictured in Figs. 111 through 118 is based on the 3CX800A7 triode. This tube has a plate dissipation of 800 W with modest cooling requirements. Requiring only 19-W drive for 700-W output, this amplifier is compatible with some of today's low-power, solid-state multi-mode transceivers.

This amplifier was originally presented in April 1984 *QST* by David D. Meacham, W6EMD. It is based on a design for the 8874 tube presented in January 1972 *QST* by Raymond F. Rinaudo, W6ZO. Most of the changes to the original design are to accommodate the larger size of the 3CX800A7 and its attendant higher capacitances and currents. Fig. 112 is the schematic diagram of the complete 3CX800A7 amplifier. A plate-current meter is not included in this design, but

Fig. 111 — Front-panel view of the 3CX800A7 2-meter amplifier.

there is room on the front panel if the builder wishes to add one.

## Construction

The amplifier chassis is mounted in a

standard 19-inch-wide, 5¼-inch-high aluminum rack panel (Bud No. SFA-1833). A 5 × 13 × 3-inch aluminum chassis (Bud No. AC-422) is spaced 1¼ inches behind the panel by two aluminum end brackets.

A 3½ × 1-inch aluminum chassis (Bud No. AC-1402) houses the input circuitry and is mounted on the larger chassis between it and the front panel. The right-

hand end bracket has a large lip on the rear for mounting the heater transformer and connectors. Fig. 113 shows mechanical details of the chassis and end brackets. The

cabinet chosen is a lightweight aluminum unit made by Ten-Tec (No. 19-0525).

### Input Circuit

In the cathode-driven configuration, the input impedance of the 3CX800A7 appears as a nominal capacitance of 26.5 pF in parallel with a resistive component that varies with operating conditions but is typically about 49 ohms. The computer-designed input circuit of this amplifier operates at a loaded Q of about 2.1. It can be set anywhere in the 2-meter band for an SWR of less than 1.3:1. C1 and C2 are predominantly matching and tuning controls, respectively; there is some interaction between them, however. When the input is tuned at 144.5 MHz, the input SWR will be less than 1.4:1 from 144 to 145 MHz.

The tube socket is an EIMAC SK-1900 or a Johnson part No. 124-311-100. Its center is mounted 2 inches from the end of the input box, adjacent to the mounting bracket. The tube pins and input circuit are cooled by a small amount of air admitted to the input box from the pressurized output box. Three holes, made with a no. 50 drill, provide adequate flow. These holes are spaced in a close triangle and are located diagonally across from the variable capacitors. Air exhausts through the tuning holes. Fig. 114 shows details of the input circuitry.

The heater circuit includes two chokes, feedthrough capacitors, the filament transformer, a voltage-dropping resistor and a switch. The chokes are wound with a turn-to-turn spacing of about one-half the wire diameter. They are self-resonant (parallel resonant) just above the 2-meter band. Nominal heater voltage for the 3CX800A7 is 13.5 V. The closest available commercial transformer has a 14.0-V secondary, so R3 is used in the primary. Switching is set up so the blower must be on before the heater can be activated. Conversely, this arrangement allows the blower to be left on after switching off the heater — a highly recommended practice.

Cathode bias is provided by a 5.1-V Zener diode, D3. R1 prevents the cathode voltage from soaring if the Zener fails. F2 will blow if excessive cathode current is drawn. R2 nearly cuts off plate current on receive. Because the grid is at dc ground, the negative supply lead must be kept above ground for grid-current metering by M1. R4 keeps the negative side of the plate supply from rising if M1, D1 and D2 all open up. D1, D2 and C3 protect the meter from transients and RF voltages.

### Output Circuit

The output tank circuit is a silver-plated quarter-wave strip line (Fig. 115) foreshortened by the tube, loading and tuning capacitances at, and near, its open end. It operates at a loaded Q of approximately 20. The silver-plated anode collet (Fig. 115) is made of 0.062-inch-thick brass sheet with Tech-Etch 134B finger stock soldered on

Fig. 114 — Close-up of the input circuitry and tube-socket wiring. Keep all leads as short as possible. Although L2 is shown here with 5 turns, the final version uses 6 turns, as described in the parts list.

the inside. It is supported by two Teflon® standoffs 1½ inch in diameter and 1 inch long. At the far end of the line, a silver-plated shorting block contacts the chassis and the strip line. This block (Fig. 115) is made from 7/16-inch-thick brass 1-5/16 inches wide and 1 inch high. EIMAC CF-800 finger stock is screwed and then soldered on both top and bottom. The chassis and strip line are both slotted to allow 5/16 inch of shorting-block travel to set the tuning range of the capacitive-tuning paddle. A 1-inch-long Teflon standoff supports the center of the line. Construction details may be seen in Fig. 117.

The tuning (C11) and loading (C10) paddles are 1-3/16-inch-diameter discs made from silver-plated, 1/16-inch-thick brass. They are spaced 1-3/8 inches center-to-center. The output loading paddle is nearest the tube, and its center is 1-13/16 inches from the tube cooler surface. Spacing between the paddle and line during operation is about 0.135 inch. The output tuning boss, EIMAC part no. 720362, is tapped

Fig. 115 — Mechanical details of the plate line, anode collet and shorting block. The plate line is made from 0.032-in-thick silver-plated brass, although copper or aluminum (5052 alloy or softer) of the same thickness may be used. The lip on the plate line is screwed to the one end of the blocking capacitors. The anode collet, which is made from 0.062-in-thick silver-plated brass, is screwed to the other ends of the blocking capacitors. Tech-Etch no. 134B finger stock soldered around the inside of the anode collet grips the 3CX800A7. Finger stock on the silver-plated brass shorting block ensures good contact between the chassis and plate line.

for a 1/4-28 threaded rod. The output loading control and output connector are two separate EIMAC assemblies combined into one unit. They are available from EIMAC as Support Assembly No. 720361 and Sliding Probe Assembly No. 720407. For this amplifier, the outer conductor was lengthened to reach the front panel. The grid collet is also available from EIMAC as part No 720359.

In addition to RFC4 and feedthrough capacitor C7, an energy-absorbing resistor (R5) is wired in series with the dc plate supply. This resistor will protect the tube and power supply in the event of a high-voltage arc. It provides necessary protection while dissipating only 12.5 W at 500-mA dc plate current.

### Cooling

The blower specified provides a measured 25 CFM airflow through the output box and tube cooler at 0.42 inch of water-column static pressure. This amount of cooling is sufficient for 800 W of plate dissipation at sea level with inlet air temperatures up to 35° C. It is adequate for the same dissipation at 5000 feet of altitude with inlet-air temperatures up to 25° C.

Not evident from the photographs is the care taken to separate outgoing hot air from incoming cool air. This is accomplished by the addition of a simple dividing wall inside the cabinet running from the rear chassis cover of the output box to the rear of the cabinet. The material used is rigid fiberglass insulation — the kind you

Fig. 116 — Mechanical details of the exhaust air RFI filter. The honeycomb material is soldered inside a 2 3/4-in OD, 0.065-in wall brass tube. The flange, which bolts to the chassis, is made from 0.125-in-thick brass sheet.

Fig. 117 — Various views of the completed 3CX800A7 amplifier.

Fig. 118 — Rear view of the amplifier with the plate-compartment cover in place. Note the honeycomb RFI filter at the hot-air exhaust.

cut with a saw. It provides a measure of blower-noise suppression in addition to assuring cool inlet air.

Hot air leaving the anode cooler is directed to a homemade "honeycomb" RFI filter through a chimney made from rolled-up Teflon sheet. The filter is made of brass tubing and sheet with the honeycomb material soldered in place. See Figs. 116 and 118 for construction details. This filter acts as a waveguide-beyond-cutoff having high attenuation at 144 MHz.

The equation for calculating attenuation by this type of filter is

$$A_a = 32 \frac{D}{d}$$

where

$A_a$  = aperture attenuation (dB)

$D$  = length of pipe

$d$  = inside diameter of pipe.

In this case, the "pipe" is each cell of the honeycomb. The basic material for the honeycomb is cadmium-plated brass heat-radiator core.<sup>1</sup> Each hexagonal-shaped cell has a width between flat sides (diameter) of 0.100 inch. The material is 1/2 inch thick.

<sup>1</sup>One source for the honeycomb radiator core material is G-O-Metric, c/o Marty Manion, 909 Norwich Ave., Delran, NJ 08075.

Plugging these values into the equation yields an  $A_a$  of 160 dB — more than enough! From a practical stand-point, it is usually sufficient to make cell length at least three times the nominal cell diameter.

#### Tune-up

Initial work may be done with a dip meter, particularly on the output circuit. With the tube in place, but with no voltages applied, the shorting block on the end of the plate line should be set to give a paddle-tuning range that straddles the desired operating frequency. Bear in mind that when the tube is "hot," the resonant frequency will be somewhat lower than it is without electron flow.

The input-tuning capacitor can be dip-meter resonated with the matching capacitor set at one-half mesh for a start. Further work here must be done "hot" with an SWR measuring device on the input.

Set the initial spacing between the output paddle and the plate line to 1/8 inch. Connect the output to a 50-ohm dummy load capable of handling at least 700 W at 144 MHz through an accurate VHF wattmeter, such as a Bird model 43. Connect a driver capable of delivering about 20 W to the input through an SWR-measuring device.

The heater of the 3CX800A7 should be run for at least three minutes before applying plate voltage. After the warm-up, short the TR terminals and apply about 1000 V to the plate. This should result in a small amount of idling plate current. Next, apply enough drive to produce a rise in plate current, and adjust the plate tuning for a peak in output power. Now tune and match the input circuit for minimum input SWR. Next, adjust the output loading paddle for maximum power output while keeping the plate current dipped with the plate tuning paddle. Apply full plate voltage and

Table 7

#### Operating Conditions for the 3CX800A7 Amplifier

Plate supply voltage	2200 V
Zero-signal plate current <sup>†</sup>	65 mA
Single-tone plate current	500 mA
Grid bias (Zener bias)	-5.1 V
Single-tone grid current <sup>†</sup>	40 mA
Driving power	18.5 W
Output power	707 W
Gain	15.8 dB
Efficiency <sup>††</sup>	64%

<sup>†</sup>Values may vary considerably from tube to tube.

<sup>††</sup>Actual tube efficiency is about one percent higher because of power loss in the 50-ohm series resistor in the plate lead (R5).

higher drive power, and then repeak the output tuning and loading controls. Touch up the input tuning and matching, and the amplifier is ready for service.

A few words of caution are in order. Remember that the heater voltage must never be applied without the blower running, and that the heater must warm up at least three minutes before applying plate voltage. Never exceed 60-mA dc grid current, even during tune-up. Also, because of the relatively low grid dissipation of the 3CX800A7, RF drive must *never* be applied unless plate voltage is applied to the tube and a suitable load is connected to the output. Following these simple rules will substantially increase tube life and amplifier reliability.

#### Typical Operating Conditions

With Zener-diode bias, the 3CX800A7 is best operated in Class AB<sub>2</sub> for linear service. The data in Table 7 represent measured performance in linear service at 144 MHz. Complete data sheets are available from EIMAC. This amplifier is easily capable of conservative operation at 700-W output. Two of these tubes will run at the 1500-W output legal limit.

# A 2-kW PEP Amplifier for 144 MHz

Large external-anode triodes in a cathode-driven configuration offer outstanding reliability, stability and ease in obtaining high power at 144 MHz.

The techniques employed in the design and construction of the cathode-driven 3CX1500A7/8877 amplifier described here (Figs. 119 to 122) have removed many of the mechanical impositions of other designs. Those interested in obtaining complete construction details should refer to the two-part article by Edward L. Meade Jr., K1AGB, appearing in December 1973 and January 1974 *QST*.

## Output Circuit

The plate tank operates with a loaded  $Q$  on the order of 40 at 2-kW PEP input and 80 at 1 kW. Typical loaded  $Q$  values of 10 to 15 are used in HF amplifiers. In comparison, we are dealing with a relatively high loaded  $Q$ , so losses in the strip-line tank-circuit components must be kept very low. To this end, small-diameter Teflon rods are used as mechanical drives for the tuning capacitor and for physical support as well as mechanical drive for the output-coupling capacitor. The tuning vane or flapper capacitor is solidly grounded through a wide flexible strap of negligible inductance, directly to the chassis in close proximity to the grid-return point. A flexible-strap arrangement, similar to that of the tuning capacitor, is used to connect the output-coupling capacitor to the center pin of a type-N coaxial connector mounted in the chassis base.

Ceramic (or Teflon) pillars, used to support the air strip line, are located under the middle set of plate-line dc isolation bushings. This places these pillars well out of the intense RF field associated with the tube, or high-impedance end of the line. In operation, plate tuning and loading is quite smooth and stable, so a high-loaded  $Q$  is apparently not bothersome in this respect.

In this amplifier, output coupling is accomplished by the capacitive probe method. Major advantages of capacitive-

Fig. 119 — Front-panel layout of the 2-meter kilowatt amplifier.

Fig. 120 — The placement of input-circuit components and supporting bracket may be seen in this bottom view. When the bottom cover is in place, the screened air inlet allows the blower to pull air in, pressurizing the entire under-chassis area. The Minibox on the rear apron is a housing for the input reflectometer circuit.

Fig. 121 — The tube and plate line is in place with the top and side of the compartment removed for clarity. The plate-tuning vane is at bottom center. A bracket is attached to the side panel to support the rear of the Teflon rod supporting the tuning vane. The coil at the opposite end of the plate line is RFC1, connected between the high-voltage-bypass plate and the top section of the plate-line sandwich. Items outside the tube enclosure include the filament transformer, blower motor, relays and a power supply to operate a VOX-controlled relay system.

**Table 8**  
**Performance Data**

	1 kW	1.6 kW
Power input, watts	1000	1600
Plate voltage	2600	2450
Plate current (single tone)	385 mA	660 mA
Plate current (idling)	50 mA	50 mA
Grid bias	-10 V	-10 V
Grid current (single tone)	35 mA	54 mA
Drive power, watts	18	41
Efficiency (apparent)	59.5%	61.8%
Power gain (apparent)	15.2 dB	13.9 dB
Power output, watts	595	1000

probe coupling are loading linearity and elimination of moving-contact surfaces.

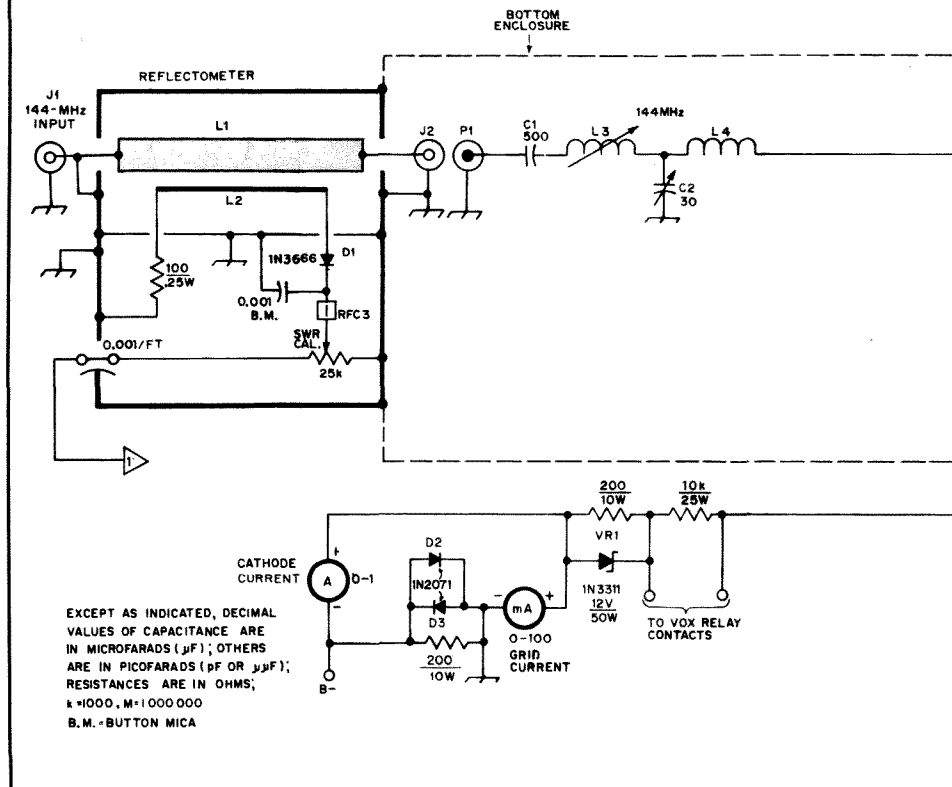

Capacitive-probe coupling is a form of reactive transformation matching whereby the feed-line (load) impedance is transformed to the tube resonant-load impedance ( $Z_o$ ) of 1800 ohms (at the 2-kW level) by means of a series reactance (a capacitor in this case).

### Support Electronics

An RF-output monitor is a virtual necessity in VHF amplifiers. In this amplifier, one of these built-in circuits is achieved quite handily. The circuit consists of a 10:1 resistive voltage divider, diode rectifier, filter and adjustable indicating instrument. Two 7500-ohm, 2-watt carbon resistors are located in the plate compartment connected between the type-N RF-output connector and a BNC connector, inside a Minibox, with the 1500-ohm, 1-watt composition resistor and the rectifier diode joined at this point. Relative output voltage is fed, via feedthrough capacitors, to the level-setting potentiometer and multimeter switch.

### Testing and Operation

The amplifier is unconditionally stable, with no parasitics. To verify this, a zero-bias check for stability was made. This involved shorting out the Zener diode in the cathode return lead, reducing bias to essentially zero volts. Plate voltage was applied, allowing the tube to dissipate about 885 watts. The input and output circuits were then tuned through their ranges with no loads attached. There was no sign of out-

put on the relative output meter and no change in the plate and grid currents. As with most cathode-driven amplifiers, there is a slight interaction between grid and plate currents during normal tune-up under RF-applied conditions. This should not be misconstrued as amplifier instability.

Tolerances of the Zener diode used in the cathode return line will result in values of bias voltage and idling plate currents other than those listed in Table 8. The 1N3311,

a 20-percent-tolerance unit, is rated at 12 volts nominal but actually operates at 10 volts in this amplifier (within the 20-percent tolerance).

To commence routine operation, the variable capacitor in the input circuit should be set at the point where lowest input SWR was obtained during the cold-tube initial tune-up. The ability of the plate tank to resonate at 144-145 MHz with the top cover in place should be verified with

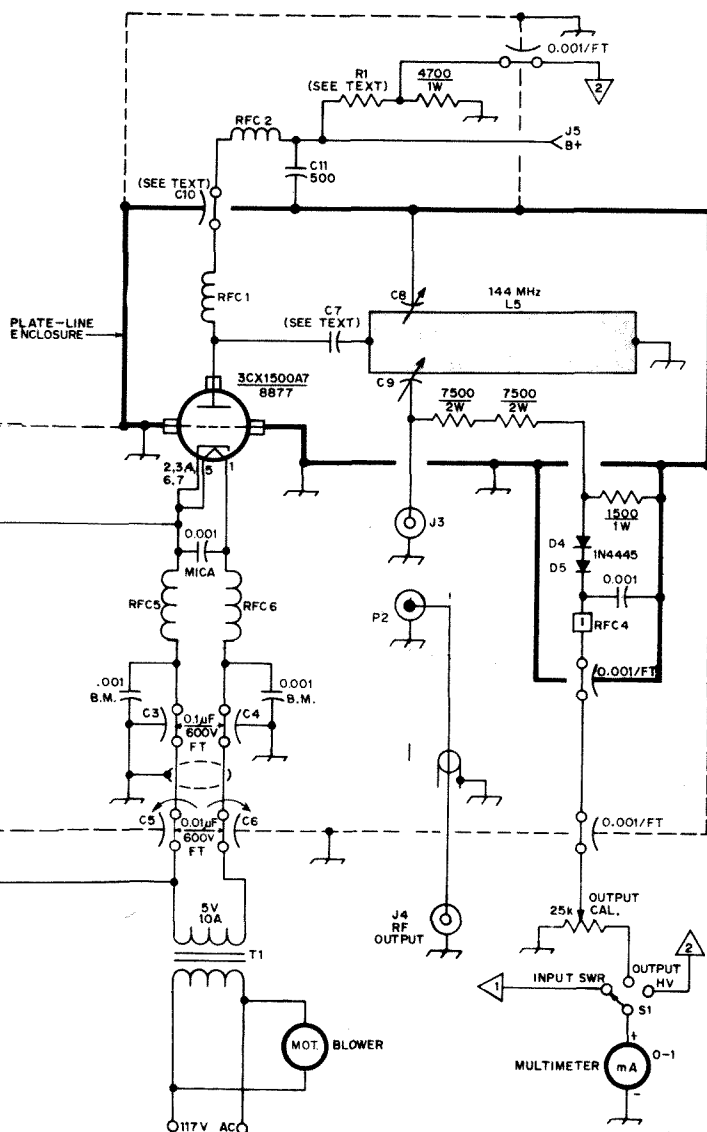

Fig. 122 — Schematic diagram of the 144-MHz amplifier. Included is information for the input reflectometer used as an aid to tuning the cathode circuit for low SWR. C7, C8 and C9 are fabricated as described in the text and Fig. 121.

- B1 — Blower, Fasco 59752-IN or Dayton 2C610. Wheel diameter is 3-3/16 inches.
- C2 — 5- to 30-pF air variable, Hammarlund HF-30-X or equiv.
- C3, C4, C5, C6 — 0.1- $\mu$ F, 600-V, 20-A feed-through capacitor. Sprague 80P3 or equiv.
- J1, J2, J6 — Type BNC.
- J3 — Type N.
- J4 — Coaxial panel jack, UG-22B/U, Amphenol 82-62 or equiv.
- J5 — HV connector, James Millen 37001 or equiv.
- L1 — Double-sided PC board, 1-1/4  $\times$  4-7/16 inches.
- L2 — 4-1/4 inches of no. 18 wire. L1 and L2 are part of the input reflectometer circuit.
- L3 — 6 turns no. 18 enam., 5/8-in long on 3/8-in-dia form (white slug).
- L4 — 3 turns no. 14 enam., 5/8 in long  $\times$  9/16-in ID. Lead length to L3 is 5/8 in. Lead length to cathode bus is 3/4 in.
- L5 — Air dielectric stripline. See text.
- P1 — Type BNC.
- P2 — Type N.
- R1 — Meter range multiplier. Ten 500-k $\Omega$ , 2-W composition resistors in series.
- RFC1 — 7 turns no. 16 tinned, 1/2-in. ID  $\times$  1-in long.
- RFC2 — 18 turns no. 18 enam., close wound on 1-M $\Omega$ , 2-watt composition resistor.
- RFC3, RFC4 — Each 2 ferrite beads on component leads.
- RFC5, RFC6 — 10 turns no. 12 enam., bifilar wound, 5/8-in dia.
- S1 — Single-pole, three-position rotary switch, non-shorting contacts.
- T1 — 5-V, 10-A secondary, center tap not used, Stancor P-6135 or equiv.

a grid-dip meter. Use a one-turn link attached to the RF output connector. Top and bottom covers are then secured. As with all cathode driven amplifiers, *excitation should never be applied when the tube heater is activated and plate voltage is removed*. Next, turn on the tube heater and blower simultaneously, allowing 90 seconds for warm-up. A plate potential between 2400 and 3000 volts then may be applied and its presence verified on the multimeter. The power supply should be able to deliver

800 mA or so. With the VOX relay actuated, resting current should be indicated on the cathode meter.

A small amount of drive is applied and the plate-tank circuit tuned for an indication of maximum relative power output. The cathode circuit can now be resonated, tuning for minimum reflected power on the reflectometer, and not for maximum drive power transfer. Tuning and loading of the plate-tank circuit follows the standard sequence for any cathode driven amplifier.

Resonance is accompanied by a moderate dip in plate/cathode current, a rise in grid current and a considerable increase in relative power output. Plate-current dip is not absolutely coincident with maximum power output, but it is very close. Tuning and output-loading adjustments should be for maximum efficiency and output as indicated on the output-meter. Final adjustment for lowest SWR at amplifier input should be done when the desired plate input-power level has been reached.

# A 220-MHz High-Power Amplifier

This amplifier employs the 3CX1500A7/8877 in a cathode-driven circuit. The grid is grounded directly to the chassis, adding to the stability. The amplifier (Figs. 123 to 127) is unconditionally stable — more so

than some amplifiers built for the HF region.

## Circuit Details

Fig. 124 is a schematic diagram of the

amplifier. The input circuit consists of a T network. Medium values of Q were chosen to provide high efficiency. Both the cathode and the heater are operated at the same RF potential; the heater is held above

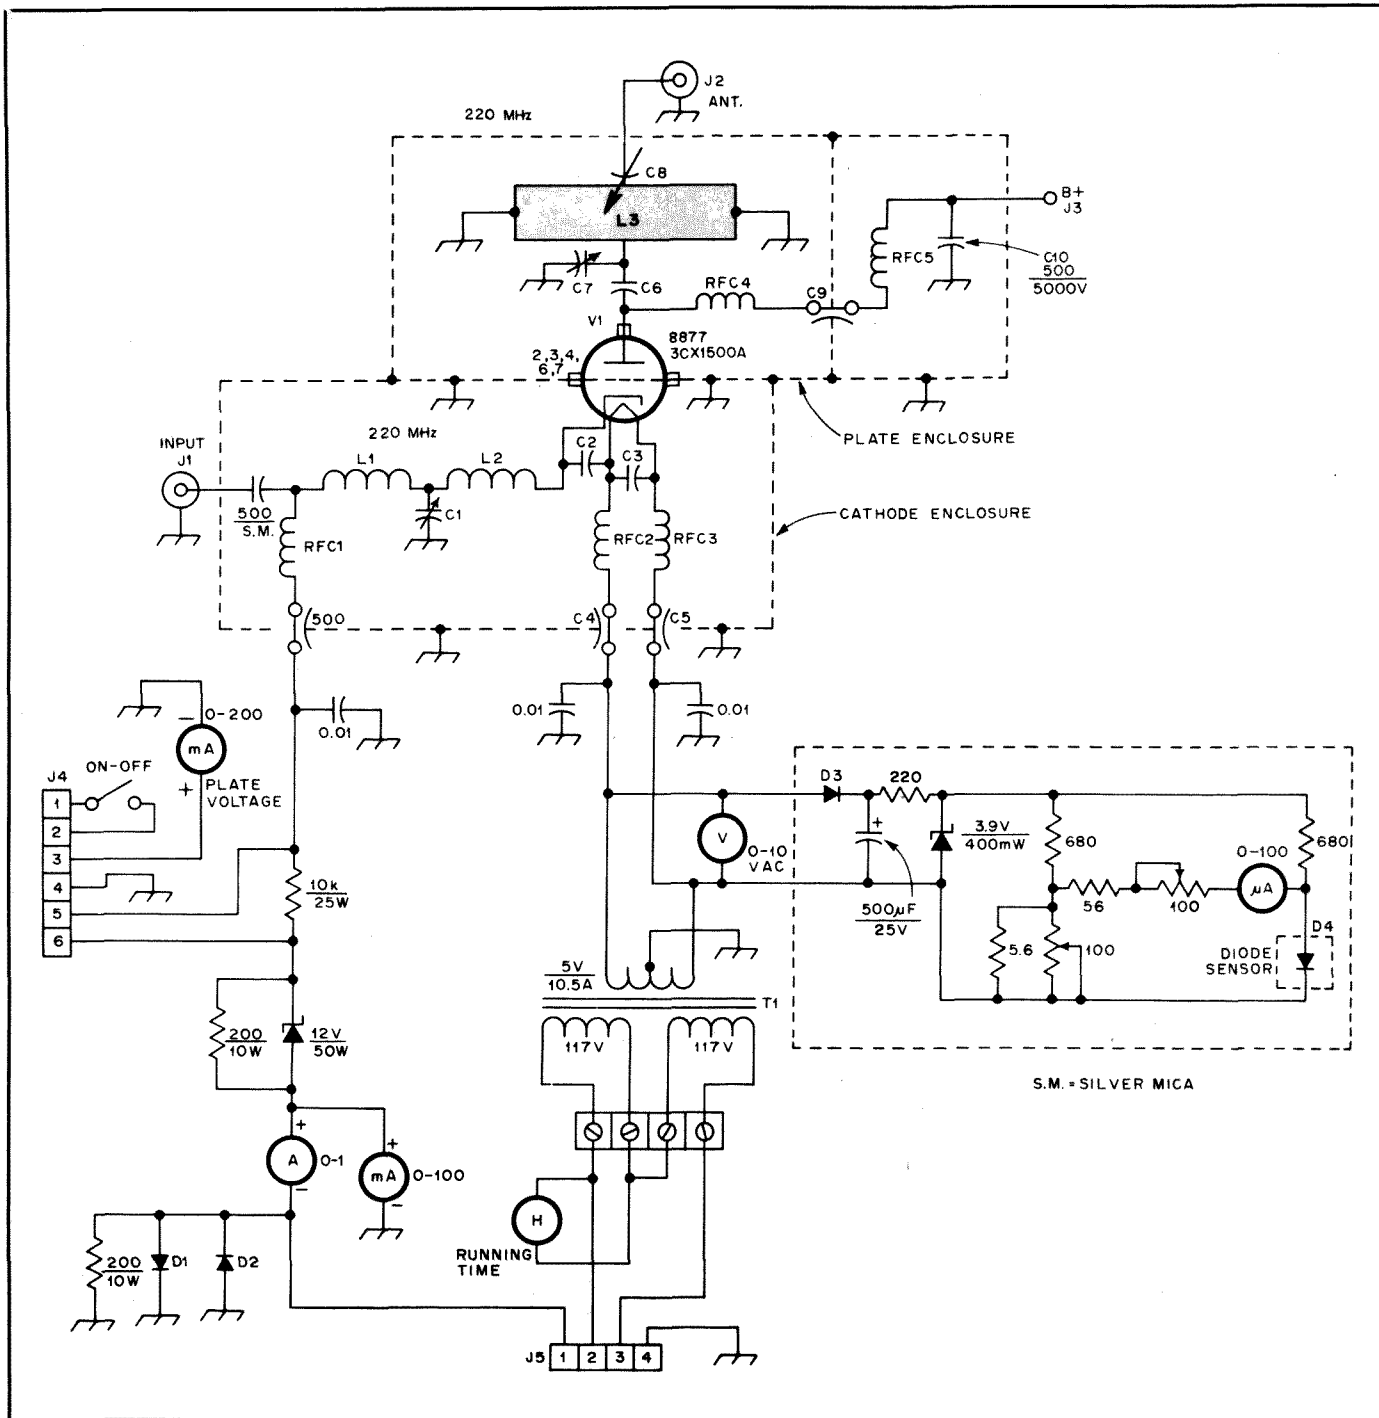

Fig. 124 — Schematic diagram of the 220-MHz amplifier. Unless otherwise specified, all capacitors are disc ceramic and resistors are 1/2-watt carbon composition.

- C1 — Air variable, 15 pF.
- C2, C3 — Button mica, 500-pF, 500-V rating.
- C4-C9, inclusive — Teflon capacitor (use 10-mil Teflon sheet).
- C10 — Doorknob capacitor, 500 pF, 5-kV rating.
- D1-D4 — 1000 PIV, 3A.

- J1, J2 — Coaxial receptacle, type N.
- J3 — High-voltage connector (Millen).
- L1 — 3 turns no. 14, 1/4-inch ID, 3/4-inch long.
- L2 — 1/4-inch-wide, 2-3/8-inch-long copper flashing strap.
- L3 — Plate inductor (see Fig. 125).
- RFC1 — 8 turns no. 18 enam. 1/2-inch dia,

- 3/4-inch long.
- RFC2, RFC3 — 10 turns no. 18 enam. bifilar wound on 3/4-inch Teflon rod close wound.
- RFC4 — 5 turns no. 16 enam. wound on 1-MΩ, 2-watt composition resistor.
- T1 — Filament transformer, 5.0 V at 10.5 A.

Fig. 123 — Front-panel layout of the 220-MHz kilowatt.

RF ground by the impedance of the filament choke. The plate tank is a pair of quarter-wavelength striplines placed symmetrically about the tube. This arrangement permits a more uniform flow of current through the anode, preventing "hot spots" on the anode conducting surface. Additionally, tube output capacitance is effectively halved, as one-half the tube capacitance (13 pF) is used to load each stripline. Striplines act as low-pass circuit elements even with the high unloaded-Q conditions found at 220 MHz. Linear inductors also offer control of odd-mode harmonics. No spurious responses could be found in this amplifier up through the 900-MHz region.

A strip-line impedance can be varied by changing its width and relation to its ground planes. Physical dimensions of the tube limit the position of the stripline above one ground plane. In order to use a commercially available chassis, the stripline was placed  $1\frac{1}{4}$  inch above one side of an inverted 4-inch-high chassis. This means that approximately 75 percent of the RF current flows through the chassis, but only 25 percent flows through the top shield cover. The small percentage flowing through the top reduces the effect of any mechanical anomalies associated with a removable cover.

For quarter-wavelength lines, the ratio of line impedance to reactance should be between 1.5 and 2.0 for the best bandwidth. Taking stray capacitance into account, expected tuning capacitance and tube output capacitance gives a value of 55 ohms for  $X_C$ . Values of line impedance versus line length for resonance at 222 MHz were computed on a programmable calculator for impedances between 30 and 100 ohms. These were plotted on a graph. Final dimensions were determined using this system, choosing dimensions that fell into the middle of the graph, thus allowing for any unpredicted effects.

Construction details are given in Figs. 125, 126 and 127. The plate blocking capacitor consists of a sandwich of brass plate and the stripline, with Teflon sheet as the dielectric. This forms a very-low-loss, high-voltage capacitor. The plate bypass capacitor is built along the same principles. A piece of circuit board was sandwiched

Fig. 125 — Bottom view of the amplifier. RFC2 and RFC3 can be seen above tube socket (bifilar winding). Copper strap is L2 shown connected to C1. Small coil is L1 and larger coil is RFC1. The grid of the tube should be grounded to the chassis with finger stock similar to that used in the plate line. Component mounted on the heat sink at left is the Zener diode used for biasing purposes.

with Teflon sheet to the side wall of the chassis. This technique is used effectively throughout as an inexpensive bypass or feedthrough capacitor at VHF.

Amplifier output is coupled through a capacitive probe. Transformation of the load impedance to the tube resonant-load impedance is achieved by means of a series reactance (the loading capacitor). The tuning capacitor is solidly grounded by means of a flexible strap of negligible inductance.

A rather elaborate metering system is employed. Although all of the meters provide useful data, only the plate and grid meters are necessary for proper amplifier use.

The anode exhaust-temperature metering circuit takes advantage of a thermal property of semiconductors. As the temperature changes, the forward resistance of a diode changes in a nearly linear manner. The diode sensor is made a part of a bridge circuit, allowing calibrated operation. Calibration may be determined by packing the diode in ice for the low point ( $0^\circ\text{C}$ ) and immersing it in boiling water for the high point ( $100^\circ\text{C}$ ). The amount of heat dissipated by the tube is inversely proportional to the efficiency for a given power input. Low heat dissipation yields longer tube life.

High-power amplifiers require considerable attention to cooling. The plate compartment is pressurized by air from an external blower. Holes in the chassis allow a portion of this air to pass through the grid and cathode structure. Most of the air

Fig. 126 — Construction details of the 220-MHz plate line and associated components.

flows through the anode, a handmade Teflon chimney, then out the top cover. Aluminum screening is tightly bonded around these two openings. No radiated RF could be detected around the chassis except within one inch of the anode exhaust hole.

To commence operation, the input should be adjusted for minimum SWR with no voltages applied. The covers should be in place whenever voltage is present. Drive should *never* be applied without plate voltage and a load connected if the filament is energized. Cooling air must always be supplied whenever the filament is turned on.

After a 60-second warmup, small amounts of drive may be applied. The plate circuit is then tuned for maximum output indication. The drive level is then increased. Tuning and loading follow the normal procedure for any cathode-driven amplifier: Adjustments are made for maximum output and efficiency. When the desired plate output power has been reached, the input circuit should be adjusted for minimum input SWR.

Fig. 127 — Interior view of the 220-MHz plate compartment. Contact of the tube with "hot side" of C6 is accomplished with suitable finger stock (available from the tube manufacturer). This conductor, in conjunction with a similar one separated by the Teflon insulator, forms the L3/C6 combination. The entire assembly is sandwiched together by means of four insulated bushings (approximately  $\frac{3}{4}$ -inch diameter). Placement of bushings is not critical. RFC4 can be seen at the right connected to C9. C8 is at the right of the photo and has a nominal spacing of 1 inch to a similar plate soldered to L3. Tuning capacitor C7 can be seen at the left connected to C6. Drive mechanism can be of builder's choice.

# A Legal-Limit 2-Meter Tetrode Amplifier

With today's typical 2-meter multimode transceiver or transverter, increasing transmit output power beyond a few hundred watts is a difficult proposition. High-level transistor "bricks" are available to raise the 10-W output from the modern transceiver to 200 W or so; an amplifier based on a member of the 4CX250 family is capable of 300 W. Going beyond this power plateau to the kilowatt level or the legal limit often requires cascades of amplifiers. The most popular types of tubes used at and beyond the kilowatt level at 144 MHz are the 8877, pairs of 8874s, and recently the 3CX800A7. While each of these tubes is of the high- $\mu$  design, with power gains approaching 16 dB, none of them is capable of producing significantly more output power than the 4CX250 when driven with only 10 W. A very popular approach is to drive a "brick" from the multimode transceiver; the brick in turn drives the triode amplifier to the desired power output.

A cleaner approach (both spectrally and in complexity) is to use a tetrode amplifier that has enough gain to develop the desired output from the 10 W available from the transceiver. The EIMAC 4CX1000A and 4CX1500B tetrodes are both capable of delivering over 1500 W output when operated class AB1. Typical realizable gain for either tube at 144 MHz is in excess of 25 dB. The amplifier shown in Figs. 128 through 150 and described here uses a 4CX1000A or 4CX1500B (the tubes are interchangeable in this design) to develop 1500-W output in linear service. The drive required to attain this output level is less than 10 W. Clarke Greene, K1JX, and Jay Rusgrove, W1VD, designed and built this project.

## Design Information

One of the main reasons for the popularity of grounded-grid triode amplifiers is the assumed inherent stability claimed for the grounded-grid circuit. There is an element of truth to that legend; since the gain of a grounded grid amplifier is almost always lower than a comparable grid-driven tetrode design, there is a larger "margin of error" available for sloppy design and construction techniques. That doesn't mean that grounded-grid triode amplifiers will not oscillate or that it is humanly impossible to make a tetrode work at high frequencies. The key consideration in maintaining stability in any kind of amplifier circuit is control of undesired feedback paths. To prevent oscillation, the gain of the amplifier in a forward direction (the desired path) must be substantially greater than the "gain" in the reverse direction. If there is sufficient leakage from the output back to the input, the stage will probably oscillate. Generally, the isolation between output and input

from feedback paths must be at least 10 dB greater than the stage gain for stable operation. For a 25-dB-gain amplifier, at least 35 dB of isolation between output and input is necessary to prevent oscillation. The grounded-grid triode amplifier, with its 16-dB stage gain, requires only about 26 dB of isolation between input and output for stability; a lot of sloppiness can be successfully tolerated.

The paths for feedback primarily take two forms: coupling between input and output caused by leakage paths, and coupling within the amplification device itself. Good construction practices can eliminate the first path through proper shielding and line bypassing. However, achieving minimal coupling through the tube itself is a challenging task. In any practical vacuum tube, parasitic reactances exist between every tube element and their connection to the outside world. The small-diameter interconnecting wires are significant fractions of a wavelength long at 144 MHz and above, and they may act as either induc-

tive elements or capacitive elements. Additionally, the interelement capacitances (for example, screen grid to control grid), while only a few picofarads, represent very low impedances at these high frequencies. A common approach to cancelling these effects is neutralization; unfortunately, most builders of high-power VHF and UHF amplifiers find neutralization a form of "black art" and are unsuccessful in attaining complete and unconditional stability as a result of their considerable efforts.

A different approach is taken here. Every effort is made to minimize feedback paths through sound design and good construction techniques. As a result, this amplifier is completely stable even without neutralization.

The first notable aspect of the amplifier is the direct grounding of the screen-grid connection to the chassis. Since the screen acts as a shield between the tube's anode and control grid (the output and input), the proper use of the screen can add significantly to output-input isolation. A very low

impedance path to ground is needed for best shielding effect. Any inductance in series between the screen connection and ground allows the screen potential to rise above ground and permits undesired coupling between anode and control grid. A (very expensive) version of the 4CX1000, the 4CX1000K, has a special screen ring built in to provide direct, low-impedance grounding of the screen grid through a matching special socket (also very expensive). Instead of using this high-priced combination, a homemade socket was fabricated to accommodate a 4CX1000A. Parts from a used standard socket were used extensively. The resulting socket, shown in the photographs and described in detail later, yields a measured isolation between amplifier output and input of greater than 40 dB at 144 MHz. Since the expected stage gain is about 25 dB, adequate isolation is available.

Fig. 131 is a schematic diagram of the amplifier RF deck. Fig. 132 shows the filament, grid and screen supplies, while Fig. 133 is a diagram of the high-voltage supply. To directly ground the screen, the tube cathode must be left floating for dc. The cathode is actually operated below dc ground by the desired tube screen potential. The cathode is grounded for RF by standard silver-mica capacitors. Since circuit circulating current is low at that point, less than perfect RF grounding causes no ill effects; any RF potential between the cathode and ground acts as degenerative feedback, only raising the amplifier's drive requirement for full output.

Both the output tank circuit and the input tank circuit are formed from dual quarter-wavelength striplines (L1, L2 and L3, L4). The circuit configuration, as described in Chapter 15, reduces the effect of tube input and output capacitances. Particularly in the input circuit where the circuit capacitance is very high, splitting the capacitance between the two lines allows for a physically manageable line, not possible with only a single quarter-wavelength line.

Historically, many amplifier builders have chosen to use a half-wavelength line at this point, letting the tube input capacitance "absorb" a large portion of the line. Tuning is then accomplished by varying a tuning capacitor at the open end of the line. Unfortunately, at frequencies well below the amplifier design frequency, the impedance to ground presented by the tuning capacitor becomes so large as to vanish. The transmission line portion of the circuit also effectively vanishes, since its inductive reactance is almost zero at low frequencies. As a result, the control grid tends to float toward infinite impedance at low frequencies. The amplifier's gain at low frequencies then becomes significantly higher than the isolation between output and input at low frequencies, and the amplifier tends to oscillate.

Several published designs have exhibited

this tendency. The only effective cure is the use of a swamping resistor across the tube control grid to reduce the amplifier's input impedance at low frequencies. The unfortunate side effect is an increase in drive level required for full output. With the grounded quarter-wavelength lines as used here, the amplifier input impedance naturally decreases below the operating frequency. At HF, the control grid is essentially grounded. No tendencies toward oscillation at any frequency have been detected in the amplifier under any conditions.

Much of the control and dc power supply circuitry is similar to that used in the Medium-Power 144-MHz Amplifier described elsewhere in this chapter. The main difference is the reference point for the various bias supplies. Since the screen is grounded for dc, both the cathode and the control grid must be operated below dc ground. Additionally, the negative side of the plate supply must be connected to the tube cathode, rather than ground. In reality, this is only a slight variation on the usual dc supply schemes. The main difference is that the reference point for zero dc potential has been changed from ground to the tube cathode (which is normally at dc ground potential). Q1 allows switching of the tube cut-off bias to be switched with reference to ground. Grounding the center contact of J1 removes cutoff bias from the tube.

### Construction Details

At first glance, this amplifier seems to require a lot of specialty components, especially the brass, copper, Teflon and G-10 stock used in the striplines and for the tuning and output coupling capacitor drive mechanisms. Fortunately, all of these materials are available in small quantities from Small Parts, Inc. The address is listed in Chapter 35.

Drawings for the required metal work are shown in Figs. 134 through 145. The main chassis that virtually everything is mounted on is  $3 \times 10 \times 17$  inches (Bud AC-416 or equiv.). The grid compartment is a similar chassis,  $2.5 \times 5 \times 13.5$  inches (Bud AC-1410 or equiv.), mounted inside the main chassis.

The plate compartment is formed from sheet aluminum bent to form walls above the main chassis. See Fig. 135. Standard construction techniques described in Chapter 24 can be used. None of the compartment dimensions is very critical from an electrical standpoint, so only mechanical considerations apply.

The tube socket is fabricated from a plate of sheet brass (Fig. 136), the grid stripline (also made from brass — see Fig. 137) and components from an EIMAC SK-800 series socket. Only the ceramic spacers, contact fingers and bayonet from the socket are used here. The predominant failure mode for a power-tetrode socket is puncture of the screen-bypass capacitor, a part not required for this design since the

Fig. 134 — General layout of the 2-meter amplifier, shown from various angles.

screen is going to be directly grounded here. Surplus sockets can often be found at very reasonable prices, with the only damage being a destroyed screen-bypass capacitor. The remaining components are perfectly suitable for use here. Complete assembly details for the socket are shown in Fig. 138.

The cathode bypass capacitors, C12 and C13, are DM-15 silver-mica units with their leads cut to 0.25 inches. The type of capacitor and lead length are somewhat critical as the lead inductances and the parasitic inductances internal to the capacitors form a series-resonant circuit at 144 MHz, yielding low impedance to ground. Other types of capacitors may be suitable, but the type suggested works very well and is reasonably priced. The capacitors are soldered between the cathode tabs on the socket and the screen contact brass piece

(Fig. 139). C8, the grid loading capacitor, is mounted in the air between J1 and the tube socket. This is a set-and-forget component. C7 is adjustable from the panel for grid tuning.

Both the plate-circuit striplines (L1, L2) and grid-circuit striplines (L3, L4) are fabricated from sheet brass (Figs. 140 and 141). Brass or nickel-plated brass hardware should be used throughout the stripline assemblies wherever the hardware comes into contact with a surface that conducts RF. Steel and other hardware will instantly heat up from flowing RF current and melt or "spark."

The blocking capacitors for both the input (C5, C6) and output (C2, C3) circuits are formed from a sandwich of 10-mil Teflon sheet between the two brass pieces that form the tuned lines. Details are given

in Figs. 140 and 141. Care should be taken when assembling these components to ensure that no metal chips embed themselves into the Teflon. Dow Corning DC-4 silicon grease should be used to coat the mating surfaces between Teflon and brass to fill in any imperfections in the surface that might allow eventual dielectric breakdown.

The plate tuning (C4) and output coupling (C1) capacitors are homemade double-plate units, also fabricated from brass sheet (Figs. 134 and 142). The flexible sections used for connecting the tuning capacitor to ground and for connecting the coupling capacitor to the output connector are made from 3-mil beryllium-copper sheet. All soldering to the plate tank circuit was done using silver solder to minimize RF and thermal resistance.

The drive mechanism for the plate-tuning capacitor (shown in Figs. 134 and 143) is made from a short section of threaded Delrin rod. The rod threads into a mating piece held fixed on the movable plate of the tuning capacitor. As the tuning control is turned, the capacitor plate moves in relation to the plate line.

The output coupling capacitor is similar in principle, except that for mechanical reasons, the movable capacitor plate is attached to a piece of 0.25-inch-thick Teflon sheet. Assembly details are shown in Figs. 134 and 144. As the two belt-coupled drive shafts rotate in parallel, the movable coupling-capacitor plate moves in relation to the fixed plate. Threaded G-10 fiberglass rods are used for the coupling-capacitor control shafts because Delrin lacked sufficient mechanical rigidity. Since the rods cross the plate tank circuit near the low-impedance ends of the plate line, no discernible heating has been observed. Mechanical stops in the form of locked pairs of nuts on the drive shafts limit the travel for the capacitor plates, preventing possible shorting of the plate voltage to ground.

The amplifier is mounted to a standard 19-inch-wide rack panel that is 8¾ inches high. Complete fabrication information for the front and rear amplifier panels is given in Fig. 145.

Most of the dc supply and control components are mounted on two etched circuit boards. Parts-placement information for these boards is given in Fig. 146. The Zener diodes for regulating the screen supply are mounted on a small aluminum plate supported by an aluminum bracket. No additional heat sinking is required. The protective components for the two panel meters (D6-D9 and 0.01-μF disc-ceramic capacitors) are mounted directly on their respective meter terminals.

Cooling for the tube is provided by an airstream that pressurizes the anode compartment. Air enters the chassis through a plastic flange (Nutone 366 or equiv.), screened with brass or aluminum screening. The majority of air passes through the tube anode cooler, through a chimney formed from 1/16-inch Teflon tape and out

Fig. 139 — Component placement around the socket. See text.

Fig. 140 — Assembly details for the grid compartment stripline.

through a screened hole in the cabinet top cover. Some of the air flows past the tube base through slots in the tube socket into the grid compartment. Eight 0.25-inch holes in the grid compartment cover plate allow sufficient air to reach the tube base. Chimney details are shown in Fig. 147. A blower could be attached directly to the back of the cabinet if the builder so desires. See Chapter 15 for information on selecting an appropriate blower.

The high-voltage supply is shown in Fig. 148. The massive Hammond transformer is bolted to the 1/4-inch-thick plate that forms the cabinet bottom. D1-D4 are mounted with thermal compound so that the chassis acts as a heat sink. C1 and C2 are mounted with aluminum straps. These capacitors were purchased surplus. Similar oil-filled capacitors are often available at flea markets at reasonable prices. Many surplus oil-filled capacitors use oil containing the carcinogenic chemical PCB, so avoid any units that are leaking. Note that the B-lead must float above dc ground in this design. Make connections between the power supply and amplifier with appropriate high-voltage wire, and ground the two chassis together for safety.

### Tune-Up and Operation

After checking all the wiring and inspecting various RF components for solid connections, a resistance check should be made of the dc blocking capacitors in the input and output circuits. The resistance (with the power supplies off and disconnected) should be infinite. Any deviation

from this high value indicates a fault somewhere in the dielectric. Any fault like this will definitely cause a failure when voltage is applied. Clear the fault before applying any voltage.

Once it has been established that there are absolutely no dc leakage paths, attach the cover plate. Connect the supply of cooling air supply (or turn on the blower) and apply filament voltage. Do not connect any other voltages at this time! After five minutes of warm-up time, the air stream exiting through the top cover should be slightly warmer than room temperature.

At this point, the input circuit can be adjusted. Attach the bottom cover and connect a 2-meter exciter to the amplifier input through an SWR indicator. About 5 W of 144-MHz drive should be applied. Adjust C7 and C8 for minimum reflected power. C7 should tune rather broadly. A near perfect match should be possible. Once the operation is complete, drive should be removed. Never apply drive to the amplifier when screen voltage is present without plate voltage or when plate voltage is present and no antenna is connected.

The two bias supplies can now be connected. These are hazardous voltages, so considerable caution should be exercised. When S2 is set so that M1 is indicating screen current, the meter should indicate approximately 30 mA. This is a normal condition. The 4CX1000A often operates under conditions of negative screen current, so a 10-k $\Omega$  load resistor is connected from the screen supply to ground to maintain screen regulation during negative screen

Table 9

### Operating Conditions for the 2-Meter 4CX1000A Amplifier

Plate voltage	3000 V
Plate current (single tone)	800 mA
Plate current (idling)	250 mA
Screen current	40 mA
Power output	1410 W
Efficiency	59%
Drive power	10 W

current conditions. This load resistor draws approximately 30 mA. As a side benefit, having the meter's zero reference lie 30 mA upscale allows for meaningful measurements of negative screen current.

Measure the filament voltage and bias voltages at the tube base. Filament voltage should be 6.0-V ac. If not, experiment with the value of the series resistor until the voltage is correct. Cathode voltage relative to ground should be approximately -280 V dc. Control grid voltage should be in the area of -500 V dc. Shorting J4 should change the control-grid voltage to about -330 V dc, variable with R1. If all the voltages are within reasonable range, final tests can be made. Turn off all power to the amplifier.

Connect the high-voltage supply to the amplifier. Connect a dummy load to J2 through a VHF wattmeter such as a Bird Model 43. Connect the exciter to J1 through another VHF wattmeter. Make sure the covers are fastened in place, and connect the air supply. Turn the filament and bias supplies on and allow the filament to warm up for 5 minutes. Assuming all is still well, gradually raise the plate voltage. Plate current as indicated by M2 should remain at zero, and neither wattmeter should show any indication. For initial testing, a plate potential of 2500 V should be used. Short J4 and adjust R1 for a resting plate current of 250 mA.

Drive may now be gently applied. Increase drive to about 1 W. Plate current should increase noticeably. Pay close attention to screen current during initial tune-up. Excessive screen current will damage a tube much more quickly than excessive plate current. Adjust C7 for maximum plate current, and then alternately adjust C1 and C4 for maximum amplifier output. Gradually increase drive while adjusting C1 and C4. Do not key the amplifier for more than about 30 seconds at a time, particularly before C1 and C4 are properly adjusted. Once full output is achieved, C8 can be readjusted for zero reflected power as seen by the exciter at full drive. Once this control is properly set, it will not require further adjustment. Proper operating conditions for the amplifier are shown in Table 9.

Spectral output of the amplifier is shown

Fig. 141 — Plate line assembly details.

in Fig. 149. The filter shown in Fig. 150 is necessary to make the amplifier meet current FCC spectral-purity requirements for commercial equipment. This amplifier has provided stable, trouble-free operation at

the legal limit for extended periods during several VHF contests and meteor showers. Although construction is a bit involved, the results are well worth the effort. This amplifier provides all the power necessary

for weak-signal 2-meter work, including EME. It is easily driven by a 10-W transverter, and the resulting signal is exceptionally clean as verified by extensive on-the-air testing with local amateurs.

# UHF and Microwave Equipment

UHF and up represents a challenge to the experimenter and builder. The techniques used at HF and VHF do not always work here. Tuned circuits for this range rarely contain coils and

capacitors as they do at HF and VHF. Sections of transmission line are used instead. Sometimes those line sections are in the form of cavity resonators. At other times, a section of line is a trace that has been

etched on a PC board.

In this chapter you will find new techniques, and old, illustrated in the various construction projects. Those projects range from simple to sophisticated.

## Dual-Gate GaAsFET Preamplifiers for 432 MHz

Dual-gate GaAsFET devices in plastic packages offer amateurs the opportunity to build inexpensive preamplifiers with good noise performance. Described here and shown in Figs. 1 through 3 are two preamplifiers that use GaAsFET devices costing only a few dollars each. These preamplifiers were designed and built by Kent Britain, WA5VJB.

### Circuit Details

The basic circuit is shown in Fig. 2. In-

formation is given so that the NEC NE41137, Motorola MRF966/967, Mitsubishi MGF1100 or 3SK97 devices may be used. C1, C2 and C5 can be miniature ceramic trimmer capacitors or piston trimmers. The exact value is not critical; any trimmer with a maximum value of 8 to 10 pF will do. C7, the output coupling capacitor, can be any small silver-mica unit between 50 and 100 pF. For stability, it is important to use good-quality capacitors for the gate 2 and source bypasses. Ceramic

chip or leadless disc-ceramic types are necessary to provide a low-impedance ground.

### Construction

The dual-gate GaAsFET preamplifiers are built "dead bug" style on a piece of double-sided PC board material. See Fig. 1. The circuit board acts as a low-impedance ground plane, and all ground connections are made directly to it. J1, J2 and C9 also secure the circuit board to the lid of the

Fig. 1 — The dual-gate GaAsFET 432-MHz preamplifier is built "dead bug" style on a piece of copper-clad circuit board material.

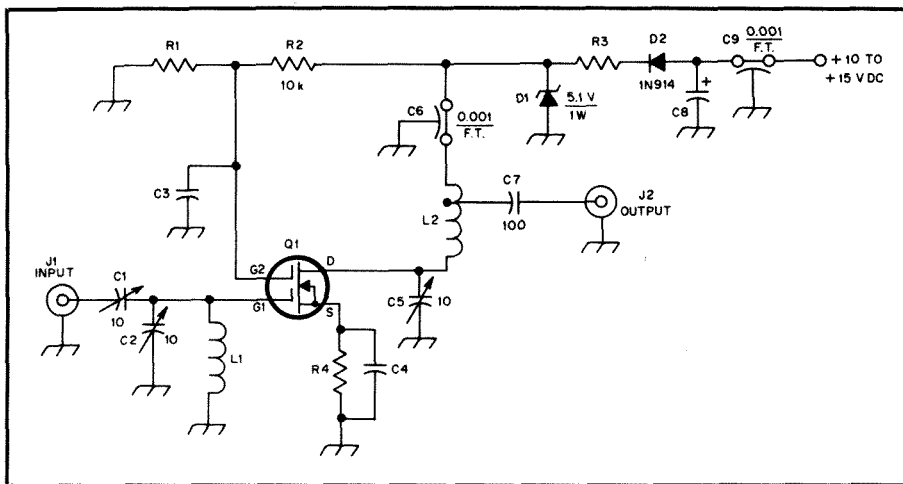

Fig. 2 — Schematic diagram of the 432-MHz dual-gate GaAsFET preamplifiers. The same circuit is used for either version, but some parts values are different. Resistors are  $\frac{1}{4}$ -W carbon composition types unless otherwise noted.

C1, C2, C5 — 10-pF (max.) trimmer capacitor.

Piston trimmer preferred, but miniature ceramic trimmer will work fine.

C3, C4 — 200- to 1000-pF ceramic chip capacitor or leadless disc-ceramic capacitor.

C6, C9 — 400- to 1000-pF feedthrough capacitor.

C7 — 50- to 100-pF silver-mica capacitor.

C8 — 1- to 25- $\mu$ F, 25-V electrolytic capacitor.

D1 — 5.1-V, 1-W Zener diode (1N4733 or equiv.).

D2 — 1N914, 1N4148 or any diode with ratings of 25 PIV and 50 mA or greater.

J1, J2 — Female chassis-mount BNC or Type-N connector.

L1 — For NE41137:  $2\frac{1}{2}$ t no. 20 copper wire, 3/16-inch ID, spaced one wire dia. For

MRF966/967: 4t no. 20 copper wire, 3/16-inch ID, spaced one wire dia. For 3SK97 or MGF1100: 2t no. 20 copper wire, 3/16-inch ID, spaced one wire dia. Tap at 1t. For MRF966/967: 2t no. 20 copper wire, 3/16-inch ID, spaced one wire dia. Tap at  $\frac{1}{2}$ t.

L2 — For NE41137, MGF1100 or 3SK97: 2t no. 20 copper wire, 3/16-inch ID, spaced one wire dia. Tap at 1t. For MRF966/967: 2t no. 20 copper wire, 3/16-inch ID, spaced one wire dia. Tap at  $\frac{1}{2}$ t.

Q1 — NEC NE41137, Motorola MRF966/967, Mitsubishi MGF1100 or 3SK97. See text.

R1 — For NE41137, MGF1100 or 3SK97: 10 k $\Omega$ ; for MRF966/967: 4.7 k $\Omega$ .

R2 — 10 k $\Omega$  for all versions.

R3 — 150- to 250-ohm, 1- or 2-W resistor.

R4 — For NE41137, MGF1100 or 3SK97: 47  $\Omega$ ; for MRF966/967: 100  $\Omega$ .

enclosure. The enclosure can be any aluminum diecast box (Bud CU-124; Hammond 1490B) or Minibox (Bud CU-3002A) approximately 4 by 2 inches, or you can make one by soldering pieces of circuit-board material together.

Q1 is supported above the ground plane by its gate 2 and source leads, which are soldered directly to C3 and C4. The other ends of these capacitors are soldered to the ground plane. R4 should be soldered in place with essentially no lead length. Placement for the rest of the parts is not critical, but keep the leads short. A layout that has proven successful is shown in Fig. 3.

GaAsFETs are static-sensitive, so handle them accordingly. See Chapter 24 for information on working with static-sensitive devices. It's best to assemble the rest of the circuit and install Q1 last. Use a grounded iron if possible, and solder the leads quickly.

Parts for this project are available from Microwave Components of Michigan and Applied Invention, both listed in Chapter 35. NEC transistors are available from California Eastern Laboratories, 3260 Jay St., Santa Clara, CA 95050.

Peak the tuning capacitors on a weak signal and adjust for best signal-to-noise ratio. For best results, you should have access to a noise-figure meter. This preamplifier typically measures 0.7- to 0.9-dB noise figure and 22- to 24-dB gain with any of the listed devices.

Fig. 3 — Suggested layout for the dual-gate GaAsFET 432-MHz amplifier. The circuit board is approximately  $1\frac{1}{4} \times 3\frac{3}{4}$  inches. J1 and J2 are approximately  $\frac{1}{4}$  inches apart.

# GaAsFET Preamplifier for 70 cm

The preamplifier described here and shown in Figs. 4 through 6 offers good noise performance and gain, and is suitable for terrestrial, EME and satellite applications at 432 and 435 MHz. Gain is approximately 15 dB and the noise figure is 0.55 dB, measured on an HP8970A noise-figure meter with the HP346A noise source. This preamplifier is easy to build and offers stable operation with little adjustment. It was designed by Chip Angle, N6CA. The version shown here was built and tested in the ARRL lab by Mark Wilson, AA2Z.

## Circuit Details

The schematic diagram of the 70-cm GaAsFET preamplifier is shown in Fig. 5. The circuit was originally designed for an NEC NE21889 GaAsFET, but a Mitsubishi MGF1402 or MGF1202 device will work fine. The version shown here uses an MGF1402, but most single-gate GaAsFETs will work.

This preamplifier uses source feedback to bring the input impedance close to 50 ohms. Input and output return loss is typically better than 15 dB. This means that a band-pass filter can be used ahead of the preamplifier without introducing mismatch loss or instability.

The design uses plenty of decoupling capacitors and RF chokes. Good-quality bypass capacitors are a must for stable operation, so use chip capacitors where specified. D1 and D2 are included for reverse and overvoltage protection. Regulator U1 allows virtually any voltage greater than 9-V dc to be used.

## Construction

The preamplifier is built on a G-10 glass-epoxy printed-circuit board using surface-mounting techniques. Layout is shown in Fig. 6. All components mount to the circuit traces. The other side of the board is unetched copper except around the connector center pins, and acts as a ground plane. All grounded pads on the etched side are connected to the ground plane with eyelets or pieces of tinned wire that pass through holes in the board and are soldered to both sides.

The board is mounted to the lid of a diecast box (Hammond 1590B or Bud CU-124) and is designed to accommodate Type-N connectors. Aluminum spacers for the connectors must be fabricated, as shown in Fig. 6. These spacers mount between the box lid and the ground plane of the PC board.

Q1 has two source leads. Only one is used on this board, and the extra lead may be clipped off. The ferrite bead on the drain lead mounts in a small hole cut in the board. The drain lead passes through this bead and is soldered to a pad.

GaAsFETs are static-sensitive, so handle them accordingly. See Chapter 24 for in-

Fig. 4 — The 70-cm GaAsFET preamplifier is built on a PC board that is mounted to the lid of a diecast box. This version uses a Zener diode instead of the 3-terminal regulator shown in Figs. 5 and 6. Connector mounting hardware also holds the board in place. Component layout is shown in Fig. 6.

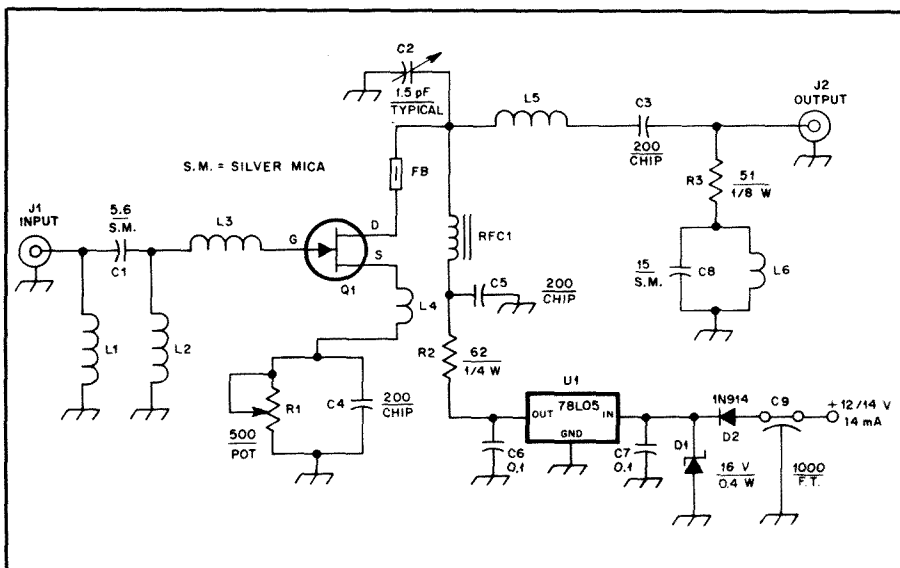

Fig. 5 — Schematic diagram of the 70-cm GaAsFET preamplifier. Resistors are carbon-composition types. Resistor values are given in ohms; capacitor values are given in pF.

- C1 — 5.6-pF silver-mica capacitor or same as C2.
- C2 — 0.6- to 6-pF ceramic piston trimmer capacitor (Johanson 5700 series or equiv.).
- C3, C4, C5 — 200-pF ceramic chip capacitor.
- C6, C7 — 0.1-μF disc ceramic capacitor, 50 V or greater.
- C8 — 15-pF silver-mica capacitor.
- C9 — 500- to 1000-pF feedthrough capacitor.
- D1 — 16- to 30-V, 500-mW Zener diode (1N966B or equiv.).
- D2 — 1N914, 1N4148 or any diode with ratings of at least 25 PIV at 50 mA or greater.
- J1, J2 — Female chassis-mount Type-N connectors, PTFE dielectric (UG-58 or equiv.).
- L1, L2 — 3T no. 24 tinned wire, 0.110-inch ID, spaced 1 wire dia.
- L3 — 5T no. 24 tinned wire, 3/16-inch ID, spaced 1 wire dia. or closer. Slightly larger diameter (0.010 inch) may be required with some FETs.
- L4 — 1T no. 24 tinned wire, 1/8-inch ID.
- L5 — 4T no. 24 tinned wire, 1/8-inch ID, spaced 1 wire dia.
- L6 — 1T no. 24 tinned wire, 1/8-inch ID.
- Q1 — Mitsubishi MGF1402 (see text).
- R1 — 200- or 500-Ω cermet potentiometer set to midrange initially.
- R2 — 62-Ω, 1/4-W resistor.
- R3 — 51-Ω, 1/8-W carbon composition resistor, 5% tolerance.
- RFC1 — 5T no. 26 enam. wire on a ferrite bead.
- U1 — 5-V, 100-mA 3-terminal regulator (LM78L05 or equiv. TO-92 package).

Fig. 6 — Parts placement diagram for the 70-cm preamplifier. A full-size etching pattern may be found at the back of this book.

formation on working with static-sensitive devices. It's best to assemble the rest of the circuit and install Q1 last. Use a grounded iron if possible, and solder the leads quickly.

Parts for this project are available from Microwave Components of Michigan and Applied Invention, both listed in Chapter 35. MGF1402 transistors are available from Advanced Receiver Research, Box 1242, Burlington, CT 06013. NEC transistors are available from California Eastern Labora-

tories, 3260 Jay St., Santa Clara, CA 95050.

#### Adjustment

The preamplifier shown in Fig. 4 was assembled in the ARRL lab and tested before any adjustments were made. For starters, C2 was set at midrange. As assembled, the preamp measured 13 dB gain with a 0.57-dB noise figure — perfectly acceptable performance for a device

such as this. After adjusting C2 and bending L3 and L5, the gain increased to 15.25 dB with a 0.54-dB noise figure. This is acceptable for all but perhaps the most demanding EME applications. No amount of spreading or compressing the coils could make the gain fall below 12 dB or the noise figure rise above 0.65 dB. At no time did the preamp display signs of instability. In short, this is a reproducible project. You can assemble it without test equipment and be reasonably sure of the performance.

# Dual-Gate GaAsFET Preamplifiers for 1296 MHz

Dual-gate GaAsFET devices in plastic packages offer amateurs the opportunity to build inexpensive UHF preamplifiers with noise figures that were unattainable a few years ago. Described here and shown in Figs. 7 through 9 are two 1296-MHz preamplifiers that use GaAsFET devices costing only a few dollars each. These preamplifiers were designed and built by Kent Britain, WA5VJB.

## Circuit Details

The basic circuit is shown in Fig. 8. Information is given so that either the NEC NE41137 or the Motorola MRF966/967 devices may be used. C1 is a piston trimmer. C2, C3 and C6 are ceramic chip capacitors. L1 and L2 are striplines made from brass or copper strips, or copper wire. For stability, it is important to use good-quality capacitors for the gate 2 and source bypasses. Ceramic chip capacitors are necessary to provide a low-impedance ground and help to avoid lead inductance problems. The value of these chip capacitors is not critical; any value between 200 and 1000 pF should work.

## Construction

The dual-gate GaAsFET preamplifiers are built "dead bug" style on a piece of double-sided PC board material. See Fig. 7. The circuit board acts as a low-impedance ground plane, and all ground connections are made directly to it. J1, J2 and C8 also secure the circuit board to the lid of the enclosure. The enclosure can be any aluminum diecast box (Bud CU-124; Hammond 1490B) or Minibox (Bud CU-3002A) approximately 4 by 2 inches, or you can make one by soldering pieces of circuit board material together.

Dimensions for the striplines should be followed carefully, especially the height above the ground plane. Note that the lengths given for L1 do not include the 3/16-inch lip that is soldered to the ground plane. Also, keep in mind that the length of L2 includes transistor lead length and should be measured from the case of Q1 to C6. The brass or copper stock for L1 and L2 should be available at hobby stores. Alternatively, it is available from Small Parts, Inc. (see Chapter 35). Although 0.020-inch-thick stock was used here, 0.010- to 0.030-inch stock will work.

Q1 is supported above the ground plane by its gate 2 and source leads, which are soldered directly to C2 and C3. The other ends of these capacitors are soldered to the ground plane. R4 should be soldered in place with essentially no lead length. For best results, follow the layout shown in Fig. 9. The most important trick is to mount J1 and J2 with their center pins 2-3/8 inches apart.

GaAsFETs are static-sensitive, so handle them accordingly. See Chapter 24 for in-

Fig. 7 — The dual-gate GaAsFET 1296-MHz preamplifier is built "dead bug" style on a piece of copper-clad circuit board material in the lid of a diecast box. See Fig. 9 for parts-placement information.

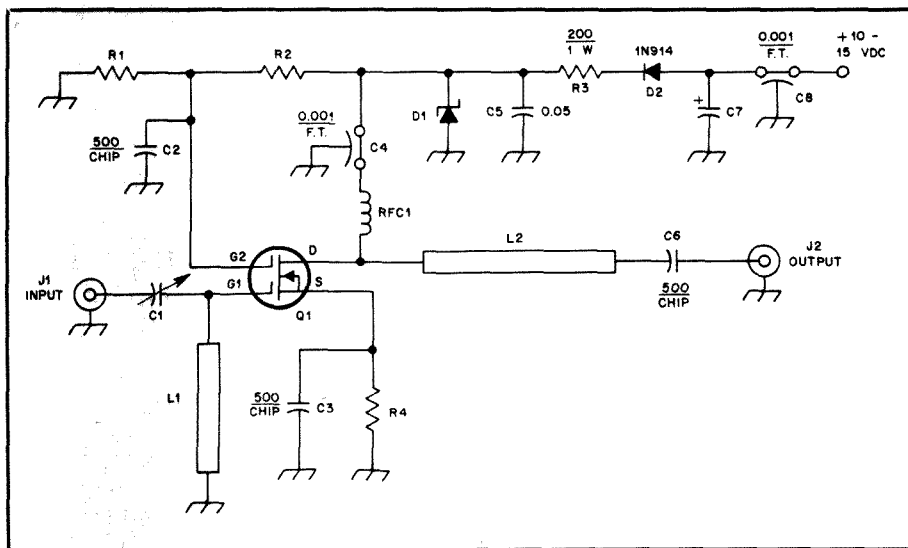

Fig. 8 — Schematic diagram of the 1296-MHz dual-gate GaAsFET preamplifiers. The same circuit is used for either version, but some parts values are different. Resistors are 1/4-W carbon-composition types unless otherwise noted.

- C1 — 10-pF (max.) piston trimmer capacitor (Johanson 5200 series, Voltronics EQT-9 or equiv.).
- C2, C3, C6 — 200- to 1000-pF ceramic chip capacitor.
- C4, C8 — 200- to 1000-pF feedthrough capacitor.
- C5 — 0.05-μF disc-ceramic capacitor.
- C7 — 1- to 20-μF, 25-V electrolytic capacitor.
- D1 — For NE41137: 4.3-V, 1-W Zener diode (1N4731 or equiv.). For MRF966/967: 5.1-V, 1-W Zener diode (1N4733 or equiv.).
- D2 — 1N914, 1N4148 or any diode with ratings of 25 PIV and 50 mA or greater.
- J1, J2 — Female chassis-mount BNC, SMA or Type-N connector.
- L1 — For NE41137: Brass or copper strip, 0.020-inch thick, 1/4-inch wide, 1-inch long (plus 3/16-inch lip), mounted 3/16-inch above the ground plane. For MRF966/967: Brass or copper strip, 0.020-inch thick, 1/4-inch wide,

- 7/8-inch long (plus 3/16-inch lip), mounted 3/16-inch above the ground plane.
- L2 — For NE41137: Piece of no. 22 copper wire, 1-1/8 inches long (measured from the body of Q1 to C6), mounted 1/4 inch above the ground plane. For MRF966/967: Brass or copper strip, 0.020-inch thick, 1/8-inch wide, 1 1/4 inches long, mounted 1/4 inch above the ground plane.
- Q1 — NEC NE41137 or Motorola MRF966/967. See text.
- R1 — For NE41137: 10 kΩ; for MRF966/967: 2.2 kΩ.
- R2 — For NE41137: 10 kΩ; for MRF966/967: 4.3 kΩ.
- R3 — 150- to 250-ohm, 1- or 2-W resistor.
- R4 — For NE41137: 47 Ω; for MRF966/967: 100 Ω.
- RFC1 — 6t no. 22 enam., 1/8-inch ID, close wound.

# A GaAsFET Preamplifier for 1296 MHz

Single-gate GaAsFET devices are readily available to amateurs. They are capable of providing the low noise figures needed for weak-signal operation, including EME and terrestrial work, at 1296 MHz. Described here and shown in Figs. 10 through 12 is a 1296-MHz preamplifier that uses the popular Mitsubishi MGF1402 transistor. Dexcel 1500 or 2500 series and NEC 700 series GaAsFETs should work as well. This project was designed and built by Kent Britain, WA5VJB.

## Circuit Details

The basic circuit is shown in Fig. 11. C1 is a piston trimmer. It must be capable of tuning to 0.5 pF or less. Typically C1 tunes between 0.5- and 1-pF at resonance. L1 and L2 are striplines made from brass or copper strips, or copper wire. C2, C3 and C4 are ceramic chip capacitors. For stability, it is important to use good-quality capacitors for the source bypasses. The MGF1402 has two source leads, so a ceramic chip capacitor is used on each lead to provide a low-impedance ground. The value of these chip capacitors is not critical; any value between 200 and 1000 pF should work.

## Construction

The GaAsFET preamplifier is built "dead bug" style on a piece of double-sided PC board material. See Fig. 10. The circuit board acts as a low-impedance ground plane, and all ground connections are made directly to it. J1, J2 and C8 also secure the circuit board to the lid of the enclosure. For best performance, Type-N or SMA connectors are recommended for J1. J2 may be a BNC connector. The enclosure can be an aluminum diecast box (Bud CU-124; Hammond 1490B) or Mini-box (Bud CU-3002A) approximately 4 by 2 inches, or you can make one by soldering pieces of circuit board material together.

Dimensions for the striplines should be followed carefully, especially the height above the ground plane. The brass or copper stock for L1 should be available at hobby stores. Alternatively, it is available from Small Parts, Inc. (see Chapter 35). Although 0.020-inch-thick stock was used here, 0.010- to 0.030-inch stock will work. If you have the equipment and inclination to experiment with GaAsFETs other than the MGF1402, you may have to cut L1 a bit long and use a piece of brass foil as a sliding short to determine the correct length. Likewise, L2 can be changed by using finer wire for more inductance or thicker wire (or a brass strip) for less inductance.

Fig. 10 — The 1296-MHz preamplifier with MGF1402 is built "dead bug" style on a piece of copper-clad circuit board material in the lid of a diecast box. See Fig. 12 for parts-placement information.

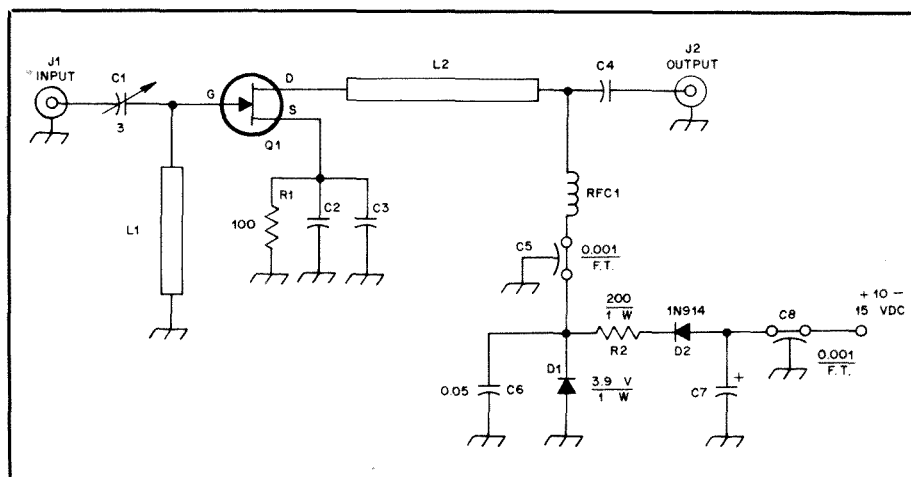

Fig. 11 — Schematic diagram of the MGF1402 1296-MHz GaAsFET preamplifier.

- C1 — 0.3- to 3-pF piston trimmer capacitor (Johanson 5800 or Giga-trim series; Voltronics EQ or M series; Erie MVM-003 series; or Johnson Teflon trimmer).
- C2, C3, C4 — 200- to 1000-pF ceramic chip capacitor.
- C5, C8 — 200- to 1000-pF feedthrough capacitor.
- C6 — 0.05-μF disc-ceramic capacitor.
- C7 — 1- to 20-μF, 25-V electrolytic capacitor.
- D1 — 3.9-V, 1-W Zener diode (1N4730 or equiv.).
- D2 — 1N914, 1N4148 or any diode with ratings of 25 PIV and 50 mA or greater.
- J1, J2 — Female chassis-mount BNC, SMA or

- Type-N connector.
- L1 — Brass or copper strip, 0.020-inch thick, 1/8-inch wide, 1 1/4 inches long (plus 1/8-inch lip), mounted 1/8 inch above the ground plane.
- L2 — Piece of no. 24 copper wire, 3/4-inch long, mounted 1/8 inch above the ground plane.
- Q1 — Mitsubishi MGF1402. See text.
- R1 — 100-Ω, 1/4- or 1/8-W, carbon-composition resistor.
- R2 — 150- to 250-ohm, 1- or 2-W resistor.
- RFC1 — 6t no. 24 enam., 1/8-inch ID, close wound.

Q1 is supported above the ground plane by its source leads, which are soldered directly to C2 and C3. The other ends of these capacitors are soldered to the ground plane. Because L1 must be mounted so close to the ground plane, C2 and C3 will probably have to be mounted at an angle.

R1 should be soldered in place with essentially no lead length. For best results, follow the layout shown in Fig. 12. The most important trick is to mount J1 and J2 with their center pins 1 3/4 inches apart.

GaAsFETs are static-sensitive, so handle them accordingly. See Chapter 24 for in-

formation on working with static-sensitive devices. It's best to assemble the rest of the circuit and install Q1 last. Use a grounded iron if possible, and solder the leads quickly.

Parts for this project are available from Microwave Components of Michigan and Applied Invention, both listed in Chapter 35. MGF 1402 transistors are available from Advanced Receiver Research, Box 1242, Burlington, CT 06013. NEC transistors are available from California Eastern Laboratories, 3260 Jay St., Santa Clara, CA 95050.

Peak C1 on a weak signal and adjust for best signal-to-noise ratio. For best results, you should have access to a noise-figure meter. This preamplifier typically provides 13- to 15-dB gain. Noise figure for this preamplifier is typically 0.8 to 0.9 dB, measured on an HP8970 noise-figure meter.

Fig. 12 — Suggested layout for the dual-gate GaAsFET 1296-MHz amplifier. The circuit board is approximately  $1\frac{1}{4} \times 3$  inches. J1 and J2 are approximately  $1\frac{3}{4}$  inches apart.

# Cost-Effective Preamp for 1296 MHz

Obtaining a low noise figure in amateur microwave receiving systems is no longer the expensive proposition it once was. The

preamplifier shown in Figs. 13, 14 and 15 is taken from a catalog of designs published by Geoffrey Krauss, WA2GFP, in June

1982 *QST*. Featuring a simple circuit using a commonly available transistor, the unit boasts a noise figure of less than 2.5 dB with a 10-dB power gain.

Construction information is given in Figs. 14 and 15, with additional instructions in the captions. All controls should be adjusted for minimum noise figure (maximum signal-to-noise ratio with a weak signal). Start with all capacitors at minimum capacitance, adjusting the output network first. Repeat the adjustments several times because they interact. R2 sets the collector current. Minimum noise figure will occur in the 3- to 7-mA range.

# Interdigital Converter for 1296 or 2304 MHz

In a world where RF spectrum pollution is becoming more serious, even into the microwave region, it is almost as important to keep unwanted signals out of a receiver as it is to prevent radiation of spurious energy. An interdigital filter was described some years ago, featuring low insertion loss, simplicity of construction, and reasonable rejection to out-of-band signals. It could be used in either transmitters or receivers.

This twice-useful principle has now been put to work again — as a mixer. Again, the ease of construction and adaptation leads many to wonder that it had not been thought of before. It was first described by W2CQH in January 1974 *QST*.

## A Filter and Mixer

A layout of the microwave portions of both converters is shown in Fig. 16. The structure consists of five interdigitated round rods, made of 3/8-inch-OD brass or copper tubing. They are soldered to two sidewalls and centrally located between two ground planes made of 1/16-inch sheet brass or copper-clad epoxy fiberglass. One ground plane is made larger than the microwave assembly and thus provides a convenient mounting plate for the remainder of the converter components.

The sidewalls are bent from 0.032-inch-thick sheet brass or they can be made from 1/4 × 3/4-inch brass rod. One edge of each sidewall is soldered to the larger ground plane. The other edge is fastened to the smaller ground plane by 4-40 machine or self-tapping screws, each located over the center line of a rod. The sidewall edges should be sanded flat, before the ground plane is attached, to assure continuous electrical contact. Note that no end walls are required since there are no electric fields in these regions.

Electrically, rods A, B and C comprise a one-stage, high-loaded-Q ( $Q_L = 100$ ), interdigital filter<sup>1</sup> that is tuned to the incoming signal frequency near 1296 or 2304 MHz. The ungrounded end of rod A

Fig. 17 — The converter for 1296 MHz. This unit was built by R. E. Fisher, W2CQH. While the mixer assembly (top center) in this model has solid brass walls, it can be made from lighter material, as explained in the text and shown in Fig. 16. The IF amplifier is near the center, just above the mixer-current-monitoring jack, J1. A BNC connector at the lower left is for 28-MHz output. The local oscillator and multiplier circuits are to the lower right. Note that L6 is very close to the chassis, just above the crystal. The variable capacitor near the crystal is an optional trimmer to adjust the oscillator to the correct frequency.

Fig. 16 — Dimensions and layout for the filter and mixer portions of the interdigital converters. The signal input is to the left rod, labeled A. Local-oscillator injection is through the diode to rod E. D1 is the mixer diode, connected to the center rod in the assembly.

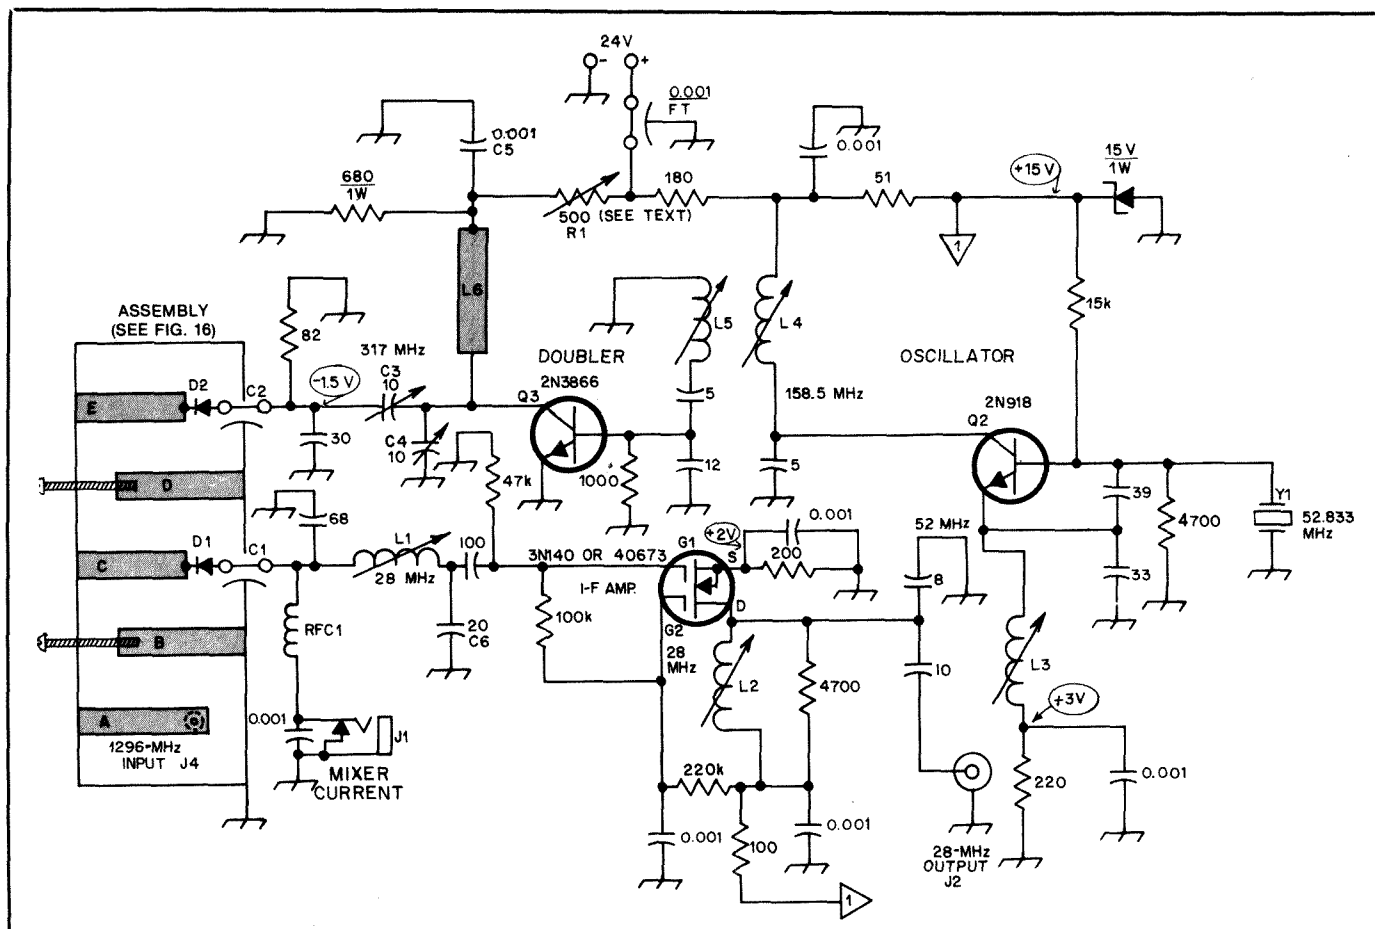

Fig. 18 — Schematic diagram of the 1296-MHz converter with oscillator and multiplier sections included. Dimensions for the filter and mixer assembly are given in Fig. 16.

is connected to a BNC coaxial connector filter input. Rod B is the high-Q resonator and is tuned by a 10-32 machine screw. Rod C provides the filter output-coupling section to the mixer diode, D1.

The original mixer diode was a Hewlett-Packard 5082-2577 Schottky-barrier type that is no longer available. The 5082-2817 and MA-4853 (Microwave Associates) are recommended substitutes. The cheaper 5082-2853 can be used instead, but this substitution will increase the 2304-MHz mixer noise figure by approximately 3 dB.

One pigtail lead of the mixer diode is tack-soldered to a copper disc on the ungrounded end of rod C. Care should be taken to keep the pigtail lead as short as possible. If rod C is machined from solid brass stock, then it is feasible to clamp one of the mixer-diode leads to the rod end with a small setscrew. This alternative method facilitates diode substitution and was used in the mixer model shown in the photograph.

Fig. 16 also shows that the other end of D1 is connected to a homemade 30-pF

Table 1  
 Converter Specifications

	1296 MHz	2304 MHz
Noise figure	5.5 dB	6.5 dB
Conversion gain	20 dB	14 dB
3-dB bandwidth	2 MHz	7 MHz
Image rejection	18 dB	30 dB
IF output	28 MHz	144 MHz

bypass capacitor, C1, which consists of a 1/2-inch-square copper or brass plate clamped to the sidewall with a 4-40 machine screw. The dielectric material is a small sheet of 0.004-in-thick Teflon® or Mylar®. A 4-40 screw passes through an oversize hole and is insulated from the other side of the wall by a small plastic shoulder washer.

In the first converter models constructed by the author and shown in the photographs, C1 was a 30-pF button mica unit soldered to the flange of a 3/8-in-diameter threaded panel bearing (H. H. Smith No. 119). The bearing was then screwed into a threaded hole in the sidewall. This provi-

sion made it convenient to measure the insertion loss and bandwidth of the interdigital filters since the capacitor assembly could be removed and replaced with a BNC connector.

Rods C, D and E comprise another high loaded-Q ( $Q_L = 100$ ) interdigital filter tuned to the local oscillator (LO) frequency. This filter passes only the fourth harmonic (1268 or 2160 MHz) from the multiplier diode, D2. The two filters have a common output-coupling section (rod C) and their loaded Qs are high enough to prevent much unwanted coupling of signal power from the antenna to the multiplier diode and LO power back out to the antenna.

The multiplier diode is connected to the driver circuitry through C2, a 30-pF bypass capacitor identical to C1. D2 is a Hewlett-Packard 5082-2811, although the 5082-2835 works nearly as well. Fifty milliwatts drive at one-quarter of the LO frequency is sufficient to produce 2 mA of mixer diode current, which represents about 1 mW of local-oscillator injection. A Schottky-barrier

diode was chosen over the more familiar varactor diode for the multiplier because it is cheaper and more stable, and requires no idler circuit.

Fig. 18 shows the schematic diagram of the 1296 to 28 MHz converter. All components are mounted on a 7 × 9-inch sheet of brass or copper-clad epoxy-fiberglass board. As mentioned earlier, this mounting plate also serves as one ground plane for the microwave mixer. When completed, the mounting plate is fastened to an inverted aluminum chassis which provides a shielded housing.

### Oscillator and Multipliers

The nonmicrowave portion of the converter is rather conventional. Q1, a dual-gate MOSFET, was chosen as the 28-MHz IF amplifier since it can provide 25 dB of gain with a 1.5 dB noise figure. The mixer diode is coupled to the first gate of Q1 by a pi-network matching section. It is most important that the proper impedance match be achieved between the mixer and IF amplifier if a low noise figure is to be obtained. In this case, the approximately 30-ohm output impedance of the mixer must be stepped up to about 1500 ohms if Q1 is to yield its rated noise figure of 1.5 dB. It is for this reason that a remote IF amplifier was not employed, as is the case with many contemporary UHF converters.

Q2 functions in an oscillator-tripler circuit that delivers about 10 mW of 158.5-MHz drive to the base of Q3. The emitter coil, L3, serves mainly as a choke to prevent the crystal from oscillating at its fundamental frequency. Coils L4 and L5, which are identical, should be placed close together so their windings almost touch.

Q3 doubles the frequency to 317 MHz, providing about 50 mW drive to the multiplier diode. It is important that the emitter lead of Q3 be kept extremely short; ¼ inch is probably too long. L6, the strip-line inductor in the collector circuit of Q3, consists of a ½ × 2½-inch piece of flashing copper spaced 1/8-inch above the ground plane. The cold end of L6 is bypassed to ground by C5, a 0.001-μF button mica capacitor.

The multiplier circuits are tuned to resonance in the usual manner by holding a wavemeter near each inductor being tuned. Resonance in the Q3 collector circuit is found by touching a VTVM probe (a resistor must be in the probe) to C2 and adjusting the Johanson capacitors until about -1.5 volts of bias is obtained. The 317- to 1268-MHz multiplier cavity is then resonated by adjusting the 10-32 machine screw until maximum mixer current is measured at J1. When resonance is found, R1 should be adjusted so that about 2 mA of mixer current is obtained. As an alter-

native to mounting a potentiometer in the converter, once a value of resistance has been found that provides correct performance it can be measured and the nearest standard fixed-value resistor substituted. Some means of adjusting the collector voltage of the multiplier stage must be provided initially to allow for the non-uniformity of transistors.

### A 2304-MHz VERSION

Figs. 19 and 20 show the schematic diagrams of the 2304-MHz converter and multiplier. The mixer and IF preamplifier were built on a separate chassis since, at the time of their construction, a multiplier chain from another project was available. An IF of 144 MHz was chosen, although 50 MHz would work as well. An IF output of 28 MHz, or lower, should not be used since this would result in undesirable interaction between the mixer and multiplier interdigital filters.

The 2304-MHz mixer and IF amplifier section, shown in Fig. 20, is very similar to its 1296-MHz counterpart. Q1, the dual-gate MOSFET, operates at 144 MHz and thus has a noise figure about 1 dB higher than that obtainable at 28 MHz.

The multiplier chain, Fig. 20, has a separate oscillator for improved drive to the 2N3866 output stage. Otherwise the circuitry is similar to the 1296-MHz version.

# 1296-MHz Transverter

Presented here is a basic 1296-MHz transverter system which, with some additions, could serve in a 1296-MHz moonbounce system. The basic unit coupled with a good antenna is capable of reasonable terrestrial performance as well. Construction requires a minimum of special skills and test equipment.

The established design specifications are listed below:

1) The unit forms the basis of a 1296-MHz weak-signal/moonbounce system.

2) The unit must be easy to build and duplicate.

3) It must be as inexpensive as possible.

4) It must use a minimum of special microwave components.

5) It must have a 28-MHz tunable IF.

6) The receiver portion should exhibit a noise figure of 3 dB or less and sufficient gain to override noise in the tunable IF. Reasonable dynamic range is also a requirement.

7) The transmitter output should be 250 mW with all spurs and harmonics down at least 40 dB.

8) The LO should produce at least +15-dBm output with all spurs and harmonics down 30 dB or more. It must be easy to align without special instruments.

9) At low microwave frequencies

lumped constants are not very effective, so microstrip techniques are used wherever possible. The microstrip portions of the circuit can be constructed easily with nothing more than a sheet of copper, some single-sided 0.062-inch G-10 (glass epoxy) board, a sharp pair of scissors, and a few tubes of Superglue! This eliminates the mess of etching PC boards.

The 1296 transverter presented here, designed and constructed by Dave Eckhardt, W6LEV, fulfills all of these requirements. The total price tag from start

to finish should be less than half the cost of comparable commercial units.

## Theory of Operation

Fig. 22 presents the block diagram of the transverter. It is broken into three major functional units. From top to bottom these are the receive chain, local oscillator (LO) and transmit chain. A photograph of the finished unit is shown in Fig. 23.

A good LO is the key to a clean transverter design. The LO used here is based on a design originally presented in *Ham Radio*.<sup>1</sup> This reference is all but required reading before tuning up the LO without special instruments. An International Crystal OE-5 modular oscillator forms the heart of the LO chain. It oscillates at 105.658333 MHz, which places 1296.000 MHz at 28.100 MHz on the tunable IF. This frequency was chosen because the band-pass filters in some receivers exhibit loss below 28 MHz. It also allows for some error in the exact LO frequency.

The price of the module is reasonable in single quantities. The output link of the OE-5 module resonates at 105 MHz, and

Fig. 23 — The completed 1296-MHz transverter consists of three circuit boards. The boards may be stacked as shown and mounted in a convenient enclosure.

<sup>1</sup>Shuch, H. P., "Compact and Clean L-Band Local Oscillators," December 1979 *Ham Radio*, p. 40.

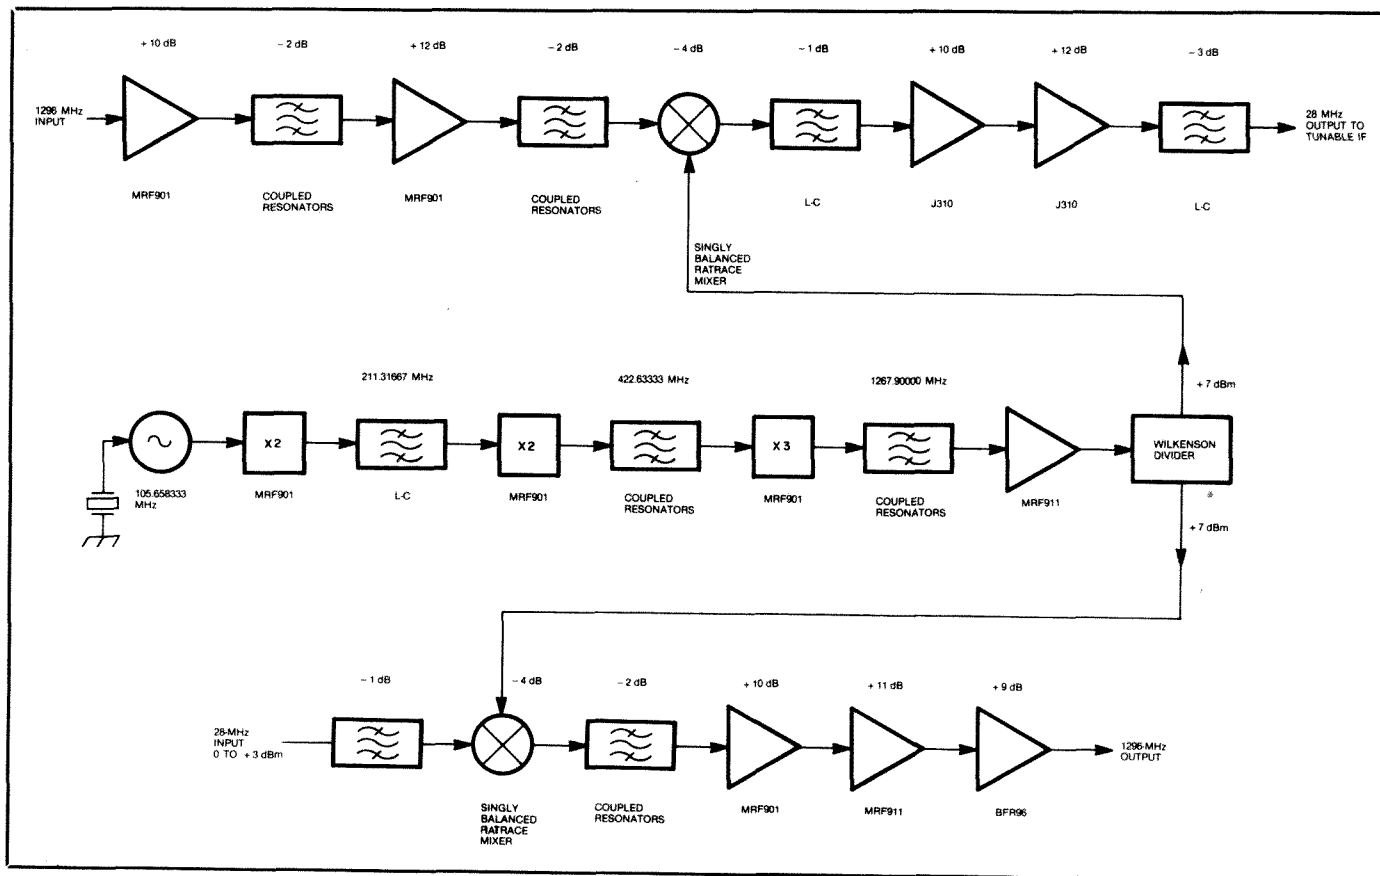

Fig. 22 — Block diagram of the 1296-MHz transverter.

feeds the first doubler. This stage tunes to 211 MHz with a single parallel-tuned resonant circuit with the inductor tapped down to feed the second doubler. The second doubler feeds a band-pass filter consisting of two inductively coupled, capacitively shortened quarter-wave stripline resonators tuned for 422.6 MHz. Output from the 422.6 MHz filter is fed to a parametric tripler which has both its input and output tuned to 1268 MHz. This technique yields about 4 dB more gain and a cleaner output than a conventional tripler. The 1268-MHz energy then passes through a 3-stage filter constructed of 0.025-inch-thick brass sheet and UT-141 semi-rigid coax. This filter was designed by Chip Angle, N6CA. The output of the filter feeds an MRF911 amplifier where the level is brought up to approximately +15 dBm. From there, the 1268-MHz signal is applied to an in-phase (Wilkinson) power divider. Each of the two output ports of the divider supply roughly +7 dBm of 1268-MHz energy to the mixers in the receive and transmit chains.

All spurs and harmonics of the LO are down 40 dB from the 1268-MHz output when tuned with the aid of a spectrum analyzer. The builder can achieve -30 dB on spurs and harmonics by following the procedure (outlined in the referenced *Ham Radio* article) for alignment without special instruments. The LO is easy to tune and achieves a clean output. It is, however, the most critical of any of the circuits in the transverter. Meticulous adherence to the outlined tune-up procedure is a must!

The receiver nominally exhibits a 3-dB noise figure with 32 dB of conversion gain. The antenna feeds the first MRF901 amplifier, which is optimized for best noise figure. Builders may want to precede the first stage with a low-loss band-pass filter, T/R switching and a GaAsFET preamplifier. Output from the noise-optimized first stage is fed through a band-pass filter identical to the 1268-MHz filter in the LO. The signal then goes to the second MRF901 amplifier, which is optimized for gain. Another band-pass filter couples the second stage to the mixer. The singly balanced rat-race mixer also accepts +7 dBm of 1268-MHz energy from one of the ports of the power divider located at the output of the LO. This type of mixer functions well with as little as +1 to +2 dBm of LO energy, but linearity and dynamic range are enhanced with +7 to +10 dBm of LO injection.

A terminating network follows the IF port of the mixer and also serves as a low-Q band-pass filter for the required difference frequency of 28 MHz. This network presents the IF port of the mixer with a constant 50-ohm load over a wide frequency range. Postconversion amplification is by means of two J310 JFETs in a common-gate configuration, with the first stage optimized for noise performance. If

the builder has a sensitive 28-MHz receiver, both stages of postconversion gain may not be required. The final block in the receiver chain is a tight band-pass filter centered on 28.5 MHz, which precedes the tunable IF.

The gain-optimized MRF901 amplifier and the two stages of postamplification gain are unconditionally stable. The noise-optimized MRF901 stage may be open- or short-circuited at its input with no damage to the device.

The transmit mixer accepts inputs from the second port of the LO power divider and 0 to +3 dBm of 28-MHz energy from the tunable IF. A terminating network/BPF identical to that in the receive chain is used at the IF port of the mixer. This mixer is identical to the receive mixer, except that the sum frequency is used. The filter that follows the RF port is, therefore, tuned to 1296 MHz, and is identical to the filters in the LO and receiver chain. The filter response is typically 15 dB down at 1268 MHz (the LO frequency) when tuned to 1296 MHz. If more attenuation is needed, two filters can be cascaded, or a high-Q open quarter-wave line cut for 1268 MHz can be installed in shunt on the filter port away from the mixer. Three stages of amplification, each supplying roughly 10 dB of unconditionally stable gain, are fed by the filter. Final output from the transmitter is between 200 and 300 mW.

## SPECIAL COMPONENTS AND TECHNIQUES

Several special techniques are used in building this transverter, but don't be alarmed! They are easy to master, and may be adapted to other UHF and microwave projects. Also, application of several special components greatly simplifies the

process of building any piece of microwave gear.

## Components

All microwave circuits require some special components, and this project is no exception. However, since most amateurs have a limited bank account (that's one reason we build), the number of special components has been kept to a minimum.

Variable capacitors that work well at microwave frequencies are quite expensive, so another method of tuning was devised. Tuning involves use of transmission-line sections and chip capacitors. The builder should have about 30 to 50 good microwave chip capacitors on hand. Not all of these will be used, but allow 30% more than needed to account for breakage or metallization separation during soldering. Don't skimp! In many cases these capacitors establish the low- and high-frequency stability of the circuits. They should *not* be the "series resonant" type, but should present a very low capacitive reactance from dc to at least 5 GHz. American Technical Ceramics makes a good line of microwave chips. Although a value of 0.01  $\mu\text{F}$  is shown in the schematics, values ranging from 0.01  $\mu\text{F}$  to 1000 pF should work well. Several of the ads in *QST* routinely carry good microwave chip capacitors ranging from \$.50 to \$1.50 each.

Special care must be exercised in soldering the chip capacitors. Fig. 24 illustrates a good technique. All surfaces should be clean and lightly tinned before you attempt to solder the chip. Position the chip in place and hold it with a toothpick. Do not use a screwdriver or tweezers, since the metal can easily damage the ceramic base of the capacitor. Lay the chisel side

Fig. 24 — A typical chip capacitor is shown at A. The proper technique for holding and soldering the chip is shown at B. At C the final appearance of the capacitor in the circuit. Check for good solder flow, no metallization separation and no cracks or fractures in the ceramic.

of the tip of a 15- to 20-watt soldering pen on the surface to which the capacitor is to be soldered, with the tip of the chisel just touching the chip capacitor.

Touch and flow a minimum amount of solder between the chip and the soldering pen tip and pull the tip away at a low angle to the surface. Repeat the procedure on the other side of the chip. If you don't dump too much heat into the chip while soldering the second end, you may not have to hold it in place. Fig. 24C illustrates how the connection should look when done. Inspect the solder and the chip capacitor with a magnifier for good solder flow and lack of fractures and cracks. Don't overheat the chip or the metallization may separate from the ceramic and you'll have to discard the capacitor. Several attempts may be necessary, but the technique can be mastered after a few tries.

In addition to chip capacitors, several high-quality microwave variable capacitors are needed. These devices are also available from some of the advertisers in *QST*. Johanson or Triko units may be used. The Johansons are more expensive, but mechanically superior. If you can tune the circuit to "perfection" with only 5 to 8 tries use the Trikos. However, they will not withstand repeated tweaking. (Who can resist?) Don't make too many substitutions of critical components unless you have some good microwave test gear.

Several feet of UT-141 semi-rigid Teflon dielectric coax is also required for resonators in the filters and interconnection between boards. Roughly 2 feet is required for the filters. In 2-foot lengths, UT-141 costs between \$1.35 to \$3 per foot. A few advertisers in *QST* offer it for sale. It is also available from most microwave parts/cabling and connector supply houses.

Order the OE-5 oscillator module directly from International Crystal. The builder may start with a good precision crystal and roll his own oscillator, but the cost difference between a high-accuracy crystal and the module is small. Drift and temperature characteristics of the OE-5 are good. The formula for the module frequency is:

$$\text{Frequency (OE-5)} = (1296.000 - \text{IF})/12$$

All frequencies are in megahertz. This should be considered if the builder desires 1296.000 MHz to fall at some frequency other than 28.100 MHz. Although I have not built this unit for the OSCAR transponder, a change in LO frequency could bring 1269 MHz in range of a 28-MHz tunable IF. All circuits should have a wide enough tuning range to accommodate the slightly lower LO and operating frequencies.

### Circuit Boards, Microstrip and Tuning

As mentioned in a previous section, much of the RF circuitry uses microstrip transmission-line sections. This was done because lumped-constant matching net-

works are not very effective at microwave frequencies. Their size is a significant portion of a wavelength, so they no longer "look like" their lumped dc equivalents. Lumped elements are available to the microwave industry, but they are generally quite expensive. The use of transmission-line sections offers a versatile, simple and inexpensive way of impedance matching and routing RF around a board. Microstrip transmission line is especially well suited because it may be etched from a double-sided copper-clad board or cut out with a sharp knife or a pair of scissors from sheet copper and mounted above the ground plane with an adhesive.

Fig. 25 shows microstrip parameters; characteristic impedance is given by Schneider.<sup>2</sup> This project assumes a dielectric constant of 4.5 for G-10 board and 1.0 for air. The width of the strip, spacing above the ground plane, and dielectric material are all variables that determine the impedance of the line and its electrical length. If a circuit is designed with this in mind, it can be tuned by tweaking the spacing or width of a line. In addition, a shunt line may be shortened or lengthened by sliding a chip capacitor up and down the line! This is the technique used to tune the transverter. It may sound odd to the uninitiated, but it works well and doesn't involve expensive gold-plated components! Most of the circuits that need tuning are designed with a shunt line and a series line with the 50-ohm port located at the end of the series line. The matching circuit variables are chosen so that the normal scatter of S-parameters from device variation is compensated for by sliding the chip capacitor up and down the shunt line until the stage is optimized. Remember to use a toothpick to hold the capacitor in place.

In the design stages of this project, this method was modeled on a Hewlett-Packard HP-41CV calculator with the aid of the Smith Chart. The method looked promising. When the original air-microstrip version was constructed, no stage took more than 5 minutes of sliding chip capacitors up and down the shunt line and "fine tuning" the spacing of the microstrip elements to optimize. When the G-10 version was constructed, the "sliding capacitor" technique proved quite adequate. This method may be applied to just about any large- or small-signal RF circuitry that uses transmission-line sections for matching.

Several characteristic line impedances are required. Table 2 presents these impedances with the required line widths and spacings. Absolute precision is not needed in cutting the line widths, but reasonable care is required. "Eyeballing" them with a ruler graduated in 0.01-inch increments is adequate. In the case of G-10 board, the spacing is always that of the board, 0.062

Fig. 25 — Microstripline physical parameters. See Table 2.

Table 2  
Microstrip Parameters

$Z_0$	Air ( $\epsilon_r = 1$ )		G-10 ( $\epsilon_r = 4.5$ )	
	w	h	w	h = 0.062
10	1.0000	0.0313		
16	1.2813	0.0625	0.5000	
18	1.1250	0.0625	0.4375	
50	0.3125	0.0625	0.1000	
70	0.3750	0.1250	0.0800	
86			0.0370	
90	0.1250	0.0625	0.030	
115	0.1563	0.125	0.016	
125	0.1250	0.1250	0.013	

inches. This project may be built with air-microstrip lines, or the lines may be mounted directly on the dielectric side of the single-sided G-10 board. In the latter case, the line length for a given electrical length of air line must be shortened by the square root of the dielectric constant. For a given electrical line length, the G-10 line is 0.471 times ( $1/\sqrt{4.5}$ ) the physical length of the corresponding air line. Therefore, for a given electrical length of line, the G-10 version occupies less than half the board space of an air-microstrip version.

In either case, the lines are simply cut to the appropriate width and length from a sheet of 1- or 2-ounce copper. If the G-10 version is built, the line is simply glued in place with Superglue. The air line version requires small spacers of 0.032, 0.062 or 0.125 inches. These are made from small ( $1/8 \times 1/8$  inch) squares of clean (no copper) 0.032, 0.062 or 0.125-inch-thick glass-epoxy board. The spacers and air line are then glued in place. A minimum number of spacers should be used. What could be easier! The ground plane on the "business side" of the G-10 board is cut from the same copper sheet to fit around and frame the microstrip elements. It is also glued in place with Superglue. It is necessary to curl the top ground over the edge of the board and solder it to the bottom ground plane. Small holes to pass no. 18 wire are drilled through both ground planes at intervals of  $1/4$  to  $1/2$  inch. This is especially important on ground-plane edges that frame microstrip elements. Short pieces of no. 18 wire (or metal grommets) are then passed through each hole, crimped with pliers, and soldered to both sides of the board.

<sup>2</sup>Hewlett Packard, HP-41CV Circuit Analysis Pac.

## Active Devices

The transverter circuitry uses only four active device types. These are the MRF901, MRF911, BFR96 and J-310. The first three are bipolar transistors and are used in the microwave circuitry. The J-310 is a JFET and is used only in the post-conversion amplifier of the receiver chain. The bipolars require a few comments.

The proper way to mount microwave devices is a bit different than for HF devices. All leads must be as short as possible and ground returns must be as direct as possible with minimum series impedance. Figs. 26 and 27 illustrate the proper way to mount the microwave devices. A hole is first drilled in the board where the transistor is to be mounted. The hole should be slightly larger than the plastic "pill." Bend the emitter lead(s) of the active device toward the bottom of the device at the pill edge and at right angles to the pill. Insert the active device into the hole. Orient the base and collector leads properly, and bend the portion of the emitter lead(s) that protrude through the bottom of the board flat with the bottom ground plane. Solder the emitter leads to the bottom ground plane.

The dc parameters of a bipolar RF device generally do not depend on the RF parameters, but the RF parameters are

Fig. 26 — Mounting technique for microwave transistors. Collector and base leads are straight; emitter leads are bent and soldered to the ground plane. See text.

Table 3

Transistor DC Bias Parameters

Device	Noise Match		Power Match	
	$V_{cc}$ (Volts)	$I_c$ (mA)	$V_{cc}$ (Volts)	$I_c$ (mA)
MRF901	6	6	10	15
MRF911			10	20
BFR 96			10	50

dependent on the dc bias parameters. Each device is characterized by the manufacturer under specific bias conditions. Although the RF parameters at this bias level (specific  $V_{cc}$  and  $I_c$ ) are closely controlled by the manufacturer, the dc parameters ( $h_{fe}$  or  $\beta$ ) of the RF devices generally are not as closely controlled. Since dc gain may vary greatly from device to device, the bias circuit must be flexible enough to set the same dc quiescent bias point in all cases. In some cases noise and gain optimization of a device require slightly different bias conditions to accommodate different high-frequency parameters. This is another way of saying "best noise performance generally does not coincide with maximum gain."

Table 3 summarizes the dc bias conditions for each bipolar transistor used in this project. These should be adhered to closely. The bias resistors shown in the schematics are those used at W6LEV. Since dc gain is not a controlled parameter, however, some minor adjustments to the bias resistors may have to be made. The dc characteristics of the devices may be determined with dc instruments and no RF drive. It is a good idea, however, to terminate each stage as it is built and during set-up with a 50-ohm resistor at input and output. Remember to block dc with a capacitor. The important parameters are collector current and collector voltage (see Table 3). The dc current gain of each device may even be measured before installing it into the circuit and the bias network "tweaked" for this gain. Remember that bipolar transistors are current-controlled, not voltage-controlled, devices. The only stage that may present a biasing problem is the BFR96. Establish the bias parameters for temperature stability.

Allow the device to warm for a few seconds after application of power to reach the stable bias point given in Table 3. This technique is preferable to letting it thermally drift through that point and run away.

## CONSTRUCTION

### 3-Element 12xx-MHz Filter

Figs. 28 and 29 illustrate the mechanical details of the 1268/1296-MHz filter that is used in four places in the transverter circuitry. The filter consists of three coupled, capacitively loaded quarter-wave resonators. The center conductor of the coax forms a tunable cylindrical capacitor at the Hi-Z end of each resonator. The only tools required are a large pair of tin snips capable of cutting 0.025-inch-thick brass sheet, a ruler, vise and 0.035- and 0.144-in drill bits. A small hammer will aid in bending the brass, and a sharp X-acto knife can be used to cut the semi-rigid UT-141 coax. All dimensions are in inches and are shown in Fig. 33. The dimensions should be followed closely — to a few hundredths of an inch is desirable.

The brass sheet should be marked and cut to size. The holes are drilled next. Do *not* bend the brass before drilling. When the brass work is finished, cut the appropriate lengths of UT-141 semi-rigid coax. It is critical to cut the correct length. Straighten a length of the coax and carefully mark off the required 1.250 inches. With the X-acto or other sharp knife, score the coax around its perimeter at the mark by rolling it on a flat surface while applying moderate pressure to the cutting edge. Once the cut has been defined around the periphery, the pressure is increased while rolling the coax until the copper tubing is cut. Be careful not to cut too deeply into

the Teflon, since the center conductor should not be cut at this point. Carefully cut through the Teflon.

To remove the coax from the bulk of the straightened portion and the center conductor, grab the length of coax to be removed lightly with a pair of pliers and pull carefully while slowly twisting it. Don't break the center conductor, since it is used to tune the resonators. Once the length of tubing and Teflon is removed, cut off the center conductor and lay both pieces aside. Repeat this procedure until the required number of resonators has been cut; three are required for each filter. Set the brass filter box on edge on a flat surface with the large holes downward and insert the lengths of semi-rigid coax into the large holes. Lightly coat the center conductors with silicone grease and insert them through the top (small) holes of the structure and into the Teflon of each resonator. The silicone grease aids in sliding the conductor in and out of the Teflon when tuning each filter. Do not insert it more than a half inch. This will hold the resonator in place while the resonators are soldered to the brass structure. Confirm that the copper of each resonator element is flush with the outer bottom surface of the brass "box." Use a 150-watt soldering gun, and solder each resonator in place from the inside of the box, making sure that the elements are parallel with the box side (the large surface) and each other. Do *not* solder the center conductors at this time.

To install the filter, set it in place on the

ground plane. Make sure the filter ground plane forms a complete sheet of copper under the filter assembly. When installed, the ground plane will form the fourth side of the box. Carefully solder the box to the ground plane continuously along each edge. Do not add so much heat that the resonators slump in position within the filter. Do not solder the center conductors.

Input and output connections to the filters are formed by soldering a short piece of large-gauge wire or a copper strip from the 50-ohm microstripline to the resonator at a point 0.250 inch from the cold end.

Filter tuning is straightforward. It is assumed that the builder has some method of sensing the amplitude of the required signal at either 1268 or 1296 MHz. This may be a selective absorption wavemeter (resonant cavity or quarter-wave line and RF probe) or a receiver (converter and tunable IF). Start with each center conductor pushed about 0.5 inch into each resonator. As the filter is tuned it is imperative that the center conductors keep good ground contact with the brass structure where they pass through it! If a good connection is not maintained, the filter will either not tune or will change tuning once the center conductors are soldered.

The builder may want to introduce a slight large radius bend in each center conductor to keep friction between the brass and each tuning element. Be sure that the center conductors are coated with silicone grease before inserting them into the resonators. Starting with the input reso-

nator, move the tuning element (center conductor) *slowly* in and out to peak the filter. Repeat for the center and output resonator. The center resonator is relatively critical, so don't use an overdamped meter movement to indicate output. Repeat the process several times, since the adjustments are interactive. *Carefully* solder each tuning element in place and cut off the excess.

### LO and Power Splitter

Fig. 30 shows the schematic of the LO and power splitter, while Fig. 31 presents the layout used in the prototype. If the layout is modified, try to stick relatively close to a left-to-right progression. This is important for a clean output. You can construct the LO a stage at a time, tune it and then proceed to the next stage until the unit is completed, or complete the unit and then tune it up. The latter is preferred since many of the adjustments interact. It is recommended that all the microstrip elements be laid out first. Then cut and glue the ground plane in place. Before mounting any components, solder the top and bottom ground planes together as described earlier with copper tape and no. 18 wire (or metal grommets). The lengths of microstripline given in Fig. 30 are for G-10 board, 0.062 inch thick.

Remove the aluminum cover from the OE-5 module and discard it. Holes must be pre-drilled in the circuit board for this component. Then mount the OE-5 module on the back of the board. A copper box (with a hole punched in it for the single adjustment) should be fabricated to enclose the oscillator. This box should be soldered to the ground plane.

The LO is the only place where high quality Johanson trimmer capacitors are used. Triko units can be used, but they are not as rugged.

Fig. 31 — Local oscillator board layout. Microstripline sections marked "50" are 50 ohms, any length. C indicates location of a chip capacitor; X indicates a jumper from top to bottom ground planes. Wrap board edges with copper and solder top and bottom.

When the unit is finished the tune-up procedure of footnote 1 should be followed. This LO will *not* perform properly when simply tuned for maximum output on a broadband power meter! Careful alignment is a must! Resist the temptation to go back and tweak. Connection to the receiver and transmitter boards should be made with short lengths of semi-rigid Teflon cable, since RG-58 foam coax is leaky at 1268 MHz.

The power divider is a standard Wilkinson in-phase divider. No alignment is necessary. The mismatch resistor between the ports should be either a 1/8-watt carbon composition unit with extremely short leads or a chip resistor.

### Mixer

The same rat-race singly balanced mixer and IF port terminator are used in both the receiver and transmitter. See Figs. 32 and 33. The LO (1268 MHz) is injected  $\frac{1}{4}$  and  $\frac{3}{4}$  wavelength from each diode (the diodes are 180 degrees out of phase with each

other). The non-microstrip side of the diodes are placed at 1296-MHz ground, but at a high impedance for the 28-MHz IF. The IF is fed through a network which theoretically maintains  $50 \pm j0$  ohms everywhere, but is transparent within its passband. It keeps the IF port at a constant impedance, which is important for proper mixer operation. The design equations for this network are given in Fig. 34. The RF is fed midway ( $\frac{1}{4}$  wavelength) from each diode.

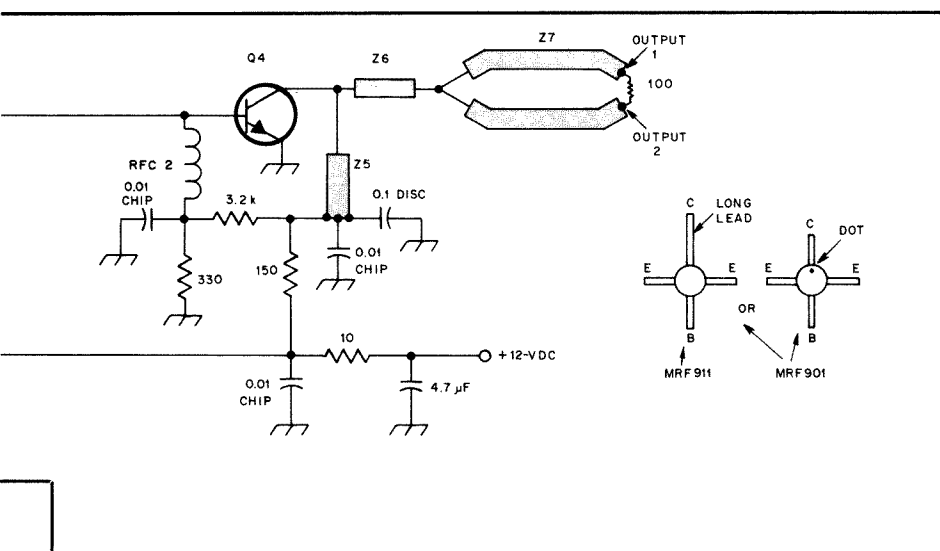

The hot-carrier Schottky diodes should be matched. This may be accomplished in a rough but satisfactory manner by choosing two diodes which exhibit the same forward dc voltage drop when biased with 5 to 10 mA of forward current.

Nominal values are given for the tuned components of the IF-port terminator. Since dip mica and chip capacitor values may vary by 5%, each tuned circuit should be adjusted to resonance with a dip meter or other means before installation. The inductor in each case may be adjusted by expanding or compressing turns. Be sure to tune each circuit with the same lead lengths that will be used when finally installed. The circuit for 28 MHz was modeled on an HP-41CV using the GNAF option of the Circuits Pac. Table 4 presents the results. Actual results on the high-frequency end will depend on component quality.

### Postconversion Amplifier and BPF

Fig. 35 shows the two stages of post-conversion amplification and output BPF. The first amplifier stage may be noise-matched to 50 ohms, if desired. As previously stated, the builder may opt to incorporate only one stage if sufficient gain and a low noise figure are present in the 28-MHz tunable IF.

The output BPF tuned components are critical. They should be tuned individually to resonance with a dip meter and frequency counter or some other method. Be sure to tune them with the same lead lengths that will be used when finally installed in the circuit. The shunt elements are especially critical. This filter may be used on other converter projects as well. For reference, Fig. 36 gives the modeled response of the

filter (HP-41CV with the LNAP option of the Circuits Pac). Actual response is very close to ideal.

### Transmitter

The transmitter board is prepared in the same manner as the LO board. See Figs. 37 and 38. It is desirable to construct the transmitter stage by stage, since problems are easier to isolate this way. The mixer, IF port terminator and first amplifier (MRF901) are constructed first. Always ter-

minate the output of the last constructed stage with a "leadless" 51-ohm 1/4-watt carbon composition resistor. First apply dc power and set the bias resistors for the collector current previously noted. Be sure it is stable with temperature. Then apply RF and adjust the sliding capacitor shunt line for maximum gain. An absorption wavemeter (cavity or quarter-wave line plus RF probe) or spectrum analyzer may be used. *Always* solder a chip capacitor at the far end of the tuned shunt line before applying power. Leave this chip in place and use another chip to fine-tune the line. Be sure to include the multiple bypass capacitors, since a 0.01- $\mu$ F chip capacitor does not supply sufficient decoupling for LF and HF.

## Receiver

If the builder has a signal source and a means of quantitative measurement, he may opt to construct the receiver stage by stage. See Figs. 39 and 40. If not, it's best to construct the entire circuit and then do the tune-up. The tuned-shunt lines are peaked in the same manner as the transmitter board. The 1296-MHz filters are tuned as previously described. You may want to vary the LO injection level. Generally, somewhere between +3 and +10 dBm injection yields quietest mixer operation. If the receiver is preceded by a GaAsFET preamplifier, the difference will be slight but noticeable over the MRF901 alone.

## Conclusion

This transverter is relatively easy and in-

Fig. 36 — Calculated response of the 28-MHz output filter.

expensive to construct. It is also relatively easy to get operating, provided good RF and microwave construction practices are followed. Various views of the completed unit are shown in Figs. 41, 42 and 44.

Useful test equipment to go along with this project include a low-pass filter and a signal source. The filter shown in Fig. 43 is taken from the RSGB *Radio Communication Handbook*. This unit has a measured insertion loss of 0.35 dB. Response is down 3 dB at 12 MHz either side of 1296 MHz and 23 dB at 1152 MHz. The filter could be built into the transverter — a lower loss cavity filter would be better if you use a GaAsFET preamplifier.

# 1296- to 144-MHz Transverter

This section describes the design and construction of a complete 1296-MHz transverter for use with any multimode 144-MHz transceiver. Integral dc and RF switching is included, so complete transverter TR control is accomplished by merely activating the transceiver PTT. The transverter is modularized to allow the individual to build just what suits his needs. This allows the builder to get on with the "barebones" transverter and build up. This project, shown in Figs. 51 through 76, was designed and built by Al Ward, WB5LUA.

## BLOCK DIAGRAM

The basic transverter is shown as the dashed area in the block diagram in Fig. 52. The unit centers around a single doubly balanced mixer (DBM) that is used as an upconverter and downconverter. The conventional approach generally has been to use separate mixers for transmit and receive. Local oscillator (LO) output is derived from a power divider. The approach taken here is to use a single mixer with both IF port and RF port switching for the up and down conversion processes. The LO starts with a 96-MHz oscillator and multiplies up to supply about +6 dBm of power at 1152 MHz to drive the mixer.

The antenna jack of the 144-MHz transceiver is connected to an IF switch that uses low-cost PIN diodes. On transmit, the switch directs the nominal 10-W 2-meter signal to an adjustable 40-dB attenuator. The attenuator output applies a nominal 1-mW (0-dBm) signal to the DBM. The 144-MHz signal is then mixed with the 1152-MHz LO signal to produce RF signals at 1296 MHz ( $RF = LO + IF$ ) and 1008 MHz ( $RF = LO - IF$ ). A cavity filter provides 28 dB of image rejection at 1008 MHz while contributing only 0.4-dB loss at 1296 MHz. After the filter, a PIN-diode RF switch directs the signal to the low-level amplifiers. The power level available to drive the low-level amplifiers is about 0.1 mW (-10 dBm).

At this point there are several options open to the builder, depending on how much power output is desired. All options shown in Fig. 52 use state-of-the-art, low-cost broadband monolithic microwave integrated circuit amplifiers (MMICs) recently released by Avantek. The MSA-0204 driving the MSA-0304 can deliver +10 dBm, which is enough to drive four MSA-0404s in a parallel configuration to 40 mW (option 1). If desired, an NEC NE41620

Fig. 51 — The various modules that make up the 1296-MHz transverter are mounted in a chassis and interconnected with short pieces of coaxial cable.

bipolar transistor amplifier can be used instead to reach the 100-mW level (option 2). The MSA-0204 and MSA-0304 are in inexpensive plastic packages and cost about \$3 each in small quantities. The MSA-0235 and MSA-0335, encased in the micro-x ceramic package, offer slightly more gain and power output, but they cost about three times as much. The 0235/0335 combination could drive four 0404s slightly harder, producing 50 to 60 mW.

The best driver for both the parallel 0404 amplifier and the NE41620 would be a single MSA-0404 running at +13 dBm, as shown in options 3 and 4. Since all of the gain available from MSA-0404 is not required, the IF drive level to the mixer should be reduced several decibels to avoid overdriving the transmitter strip.

The MSA-0404 costs about \$3.25 in single quantities, making the component price of the parallel amplifier \$13. The NEC NE41620 costs about \$16 each in small quantities. The advantage of the parallel MSA-0404 amplifier is that no tuning whatsoever is required to attain the power level. The NE41620 offers higher power that can be used to drive additional transistor amplifiers to higher output. Ac-

tual MMIC performance will be discussed at length later.

On the receive side, the HXTR-3101 RF preamplifier helps establish front-end noise figure. The noise figure of the preamplifier by itself is 2 dB. Preamplifier output is routed to the PIN diode RF switch. On receive, the signal from the preamplifier is sent through the RF filter, where 28 dB of image rejection is obtained. The RF is then down converted in the mixer to the IF frequency of 144 MHz. The PIN diode IF switch directs the signal to the low-noise 144-MHz IF amplifier. Output from this amplifier is then switched via another PIN diode switch to the antenna jack of the 2-meter transceiver used as the IF.

If the HXTR-3101 front-end RF amplifier were not used, the SSB noise figure would be approximately 11 to 12 dB depending on cable losses and type of doubly balanced mixer used. Adding the preamplifier brings the overall receiver noise figure down to a reasonable 5 to 6 dB, which is typical of the many commercial transverters available on the market today. Adding a good low noise GaAsFET preamplifier will bring the noise figure down to under 1 dB.

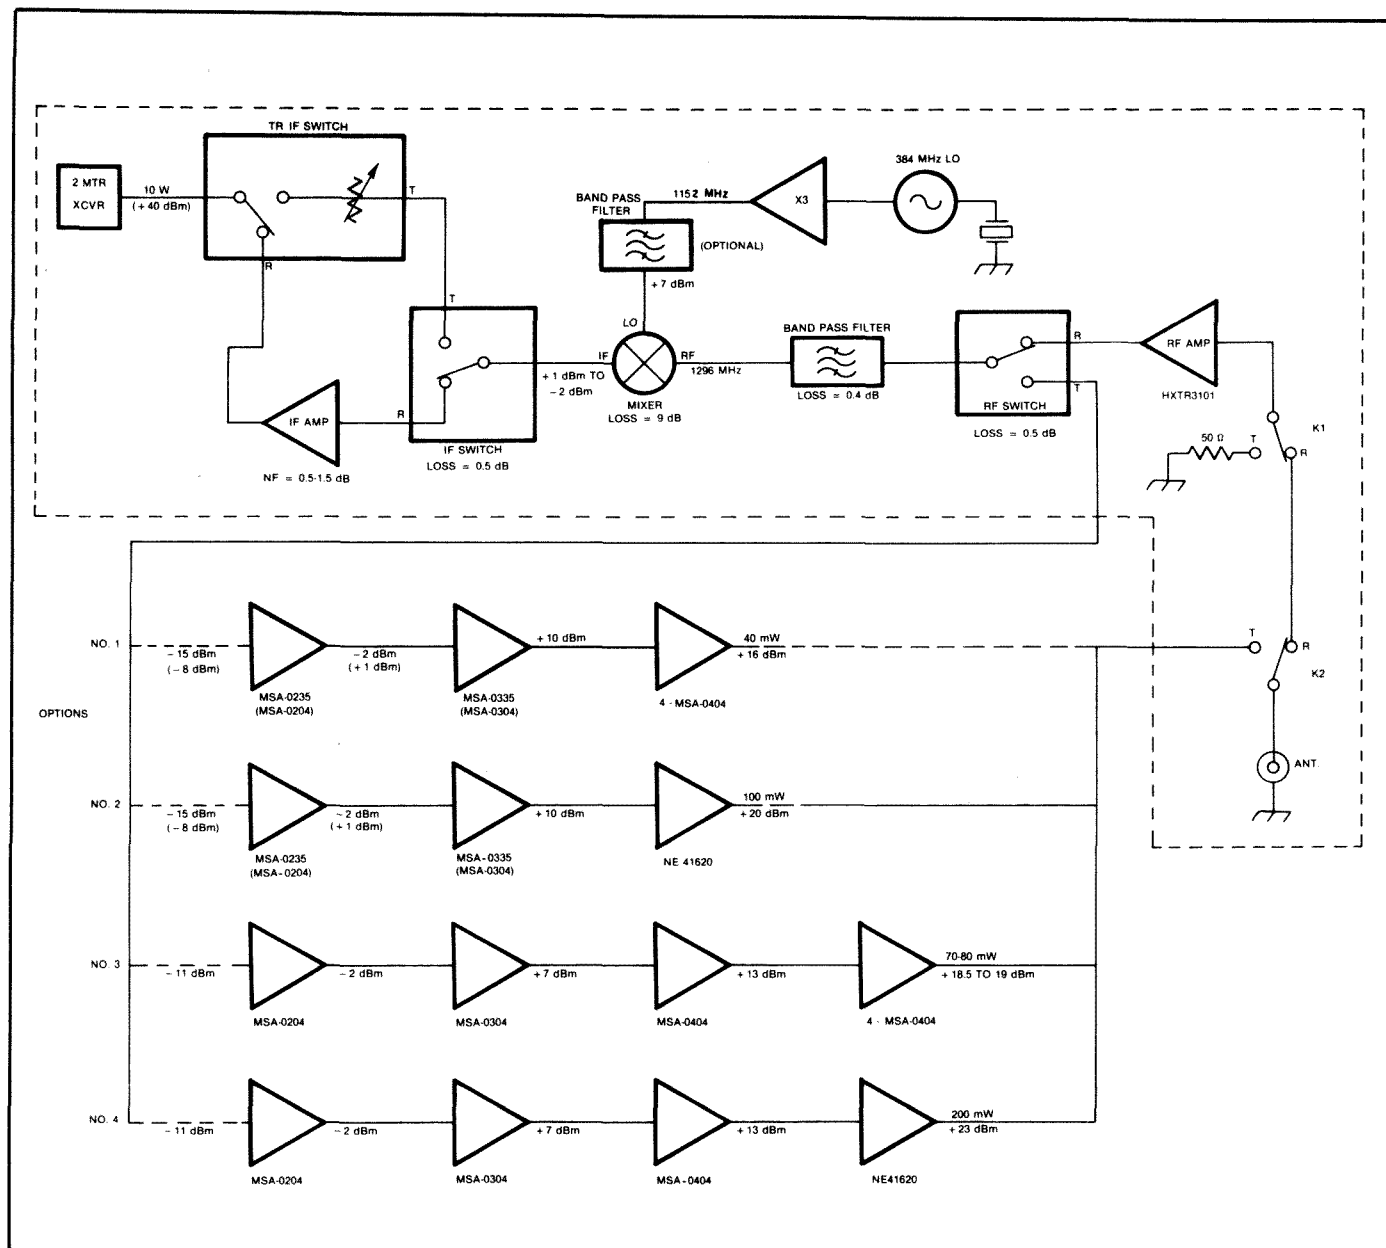

Fig. 52 — Block diagram of the 1296-MHz transverter.

Each section of the transverter is covered separately and completely with respect to description of operation, design, construction and tune-up. This should enhance the ability of the builder to construct and tune up each module separately.

### 1152-MHz LOCAL OSCILLATOR

The LO shown in Fig. 53 produces +6 to +8 dBm at 1152 MHz with inexpensive devices. The power level is adequate to drive any of the popular commercially available low-power doubly balanced mixers.

For ease of tune-up, the tripler should be built as a separate module. The 384-MHz unit produces an output power level of +7 dBm into a 50-ohm termination. When tuned up with the aid of a spectrum analyzer, all harmonics are 40 dB below the desired output. When a spectrum analyzer is not available and all tuned circuits are peaked for maximum 384-MHz output, the undesired harmonics will be approximately 30 dB below the desired signal. This is still quite acceptable because the harmonics will be suppressed even further

by the addition of the tripler stage.

The 384-MHz-to-1152-MHz tripler was designed by John Stankus, KN5N. The design goal was simplicity and conversion efficiency. This was accomplished by using a Motorola MRF901 in the circuit shown in Fig. 53. The multiplier has a power output of +6 dBm to +8 dBm into a 50-ohm termination when driven with +4 dBm at 384 MHz. The multiplier uses a parallel tuned output network and a low-pass filter input network. Without any additional filtering, the simple network will deliver the harmonic rejection shown below:

Frequency	Rejection
384 MHz	-16 dBc
768 MHz	-30 dBc
1536 MHz	-23 dBc

The results show what can be achieved with very simple tuned circuits. If additional rejection is deemed necessary, a cavity filter similar to that used on the RF port of the mixer can be inserted between the multiplier and the LO port of the mixer. The author has used the LO chain described here without additional filtering for

two years with no problems from spurious signals.

### Circuit Description

For 1296-MHz operation, an LO injection frequency of 1152 MHz is required. The basic oscillator uses a 96.0-MHz overtone crystal. For satellite Mode L operation at 1269 MHz, a 93.6667 MHz overtone crystal will be required, assuming an IF of 145 MHz is used. If you want to operate on both band segments, you can build the LO with a crystal for each and use a miniature DPDT toggle switch to switch between

them. If desired, PIN diodes can be used to switch crystals. The mechanical switch was chosen for simplicity, and it created no stability problems. Voltage to the oscillator is regulated at 9 V by D1.

The crystal frequencies are close enough that one setting of L1 produces maximum power output and easy crystal starting. Q1 can be a 2N918, MPS3563 or equivalent device. Any lower subharmonic of the crystal frequency is not suggested as this will only make adequate harmonic rejection harder to obtain.

Capacitive divider C1 and C2 matches the input of Q2, which again can be a 2N918 or MPS3563. The interstage matching network between Q2 and Q3 is a two-pole filter composed of L2-C3 and L3-C4 tuned to 192 MHz. The last doubler uses an MRF901 with another two-pole filter composed of C5-L4 and C6-L5 tuned to 384 MHz. The output is tapped halfway up on L5 to maximize output into a 50-ohm termination.

The tripler (Q4) also uses an MRF901. The input network is a standard low-pass filter to match to 50 ohms. L7 acts as an RF choke, and the 820-ohm resistor insures stability. Network C9-L9 forms a parallel-tuned filter at 1152 MHz. The quarter wave 100-ohm line (Z1) and series capacitor C11 transform the required 50-ohm output impedance up to a level required to enhance harmonic output of the MRF901. Depending on the lead inductance of C11, the output may be overcoupled and the power output at 1152 MHz low. If this is the case, change C11 to a 1-pF chip capacitor and retune the output.

### Construction

The basic 384-MHz local-oscillator assembly is built in a 2-3/8 × 5-3/8 × 1-inch box that was found surplus. The tripler was built in a 1 3/4 × 3 1/2 × 3/4-inch box made from circuit board material. The builder may use any aluminum diecast box or Mini-box of appropriate dimensions. SMA connectors were used for size considerations. BNC connectors should work as well.

As with all UHF circuitry, use the shortest lead lengths possible. There are two options available to the builder for producing Z1. The first option, which was used by KN5N in his original design, is a microstripline 0.050 inches wide by 1.9 inches long etched on 0.062-inch thick Duroid 5880 dielectric material ( $\epsilon_r = 2.2$ ). The second option, used by the author, is a 1.7-inch length of 0.141-inch, 50-ohm semi-rigid miniature hardline (UT-141). To make this line the right impedance, remove the center conductor and replace it with a 0.010-inch-diameter (no. 30) copper wire of similar length. The small-diameter wire raised the coaxial impedance to approxi-

Fig. 54 — The 384-MHz LO and tripler are built in separate enclosures.

mately 100 ohms. L9 is simply a 0.3-inch length of no. 24 wire soldered between the top of piston trimer C7 and the ground plane. The finished LO is shown in Fig. 54.

### Tune-Up

Initially, the 96-MHz crystal oscillator is best adjusted by peaking L1 with a dip meter operating as a detector. Start with C1 and C2 near minimum capacitance. After L1 is peaked, C1 and C2 are adjusted to maximize the voltage across the 220-ohm resistor in the emitter lead of Q2. In a similar fashion, maximize Q3 collector current by adjusting C3 and C4. Finally, C5 and C6 are adjusted for maximum output at 384 MHz. Harmonics should be 30 dB down from the 384 MHz signal. With the aid of a spectrum analyzer, harmonic rejection of 40 dB can be achieved. When the basic local oscillator is running properly, typical Q1 collector current is 6-10 mA for +7 dBm of output power. Total current drawn by Zener diode D1 and Q1 will be approximately 32 mA. Q2 collector current will be 9-10 mA typically. Q3 collector current will be 17-20 mA, typically, for +7 dBm output power. If you experience low 384-MHz output power, try the following. Change the 1-pF capacitor between L4, C5 and C6, L5 to a 2-pF silver-mica or ceramic unit and retune the output network.

When the 384-MHz assembly is operating properly, insert a 6-dB attenuator between the 384-MHz output and the tripler

input. This attenuator value can be optimized later, as the tripler typically requires +1 to +4 dBm to drive it to full output. The MRF901 is capable of continuous collector current of only 30 mA. Typically, 20 to 24 mA is the maximum desired. With this in mind, tune C7 and C8 to increase Q4 collector current, then tune C9 for maximum output at 1152 MHz. About +6 to +8 dBm of 1152-MHz power will be obtained with 20 to 24 mA of collector current.

Adjust the input attenuator as required to insure that the MRF901 collector current will not exceed 20 to 24 mA. With minimal adjustment, the LO can be tuned for equivalent power levels at 1152 MHz (1296-MHz operation) and 1124 MHz (1269-MHz operation).

### DOUBLY BALANCED MIXER

One of the main reasons for using a commercially available doubly balanced mixer was size. The typical DBM is quite a bit smaller than the commonly used singly balanced rat-race mixer. A DBM can easily be mounted with SMA connectors in a small 1.4 × 2.25-inch diecast aluminum box.

Most DBMs have a broad frequency response because of the inherently broadband nature of the toroidal transformers used. A schematic diagram of a typical DBM is shown in Fig. 55. No tuning is required. Fig. 56 shows the mixer used here.

The balanced nature of the DBM is the characteristic that determines the magnitude of the isolation between each of the three ports. Typically, 15 to 25 dB of isolation is the minimum desired to reduce interaction at each of the mixer ports. Typical conversion losses of 7 to 10 dB are possible with SWRs of 2:1 to 3:1.

The main drawback to a commercial DBM is cost. Most DBMs that are rated to 1300 MHz cost at least \$20 in single quantities. Careful research with several mixer manufacturers has revealed that several DBMs that are advertised to operate up to 1 GHz can still produce adequate performance at 1300 MHz.

Table 6 summarizes mixers available from several manufacturers. All mixers except the Tele-Tech MT55L require +7 dBm of LO power. Even the mixers that are running at a higher frequency than advertised still produce acceptable conversion loss performance at 1300 MHz. Most likely, the isolation and SWR characteristics are slightly worse. Two mixers stand out as high performers for low cost — the Mini-Circuits SBL-1X and the Tele-Tech MT57. The SBL-1X has been tried by WSETG with good results, so 9-dB conversion loss should be attainable. The MT57 has not been tried but should work as well. The SBL-1X is available in the standard 8-pin relay package, while the MT-57 is available in a TO-5 package.

Mini-Circuits and Tele-Tech have no minimum-order requirement; both will deal factory-direct. Just be sure to include enough extra money for postage and handling. Synergy sells direct but presently has a \$50 minimum-order requirement.

## TRANSMIT/RECEIVE IF SWITCH

The IF switching arrangement described here performs the important function of mating the 2-meter transceiver to the doubly balanced mixer. See Fig. 57. In the transmit mode, the 10-W 2-meter signal is switched to an attenuator through D1, a high-power solid-state TR switch. The attenuated signal is routed through a low-power PIN diode switch (D2 and D3) to feed the IF port of the mixer. In the receive mode, the IF signal from the mixer is fed through the low-power PIN diode switch to a low noise, dual-gate FET IF amplifier. The output of the IF amplifier is fed to the 2-meter transceiver via the high-power PIN diode switch.

The high-power MA-8334 series multi-throw switches use high-breakdown-voltage PIN diode chips. Two package styles are available, along with several switch configurations. Two types are applicable for this project. A 10-W version (MA-8334-100) is available in a 0.350-inch-diameter can. A 100-W version (MA-8334-001) is available in a package that lends itself to microstripline applications. The -100 style is adequate for the power levels encountered here.

Fig. 55 — Schematic diagram of the circuit inside a typical doubly balanced mixer module.

Fig. 56 — Typical DBMs and method of mounting with SMA connectors.

The low-power glass PIN diodes are either Microwave Associates part number MA47047, 47110, 47123 or Hewlett Packard HP5082-3379. These diodes cost about \$2 in small quantities and are

available from local distributors.

For a typical doubly balanced mixer running at +7 dBm LO power, a good rule of thumb is to not exceed +1 dBm IF input power when the mixer is run as an up-converter. With the 2-meter transceiver running at full power (typically 10 W or so), adjust CI for 0 dBm (1 mW) at the mixer.

The receive side of the IF switch includes a low-noise IF amplifier using an inexpensive 3N204 or 3N211 dual-gate FET device. The circuit is as shown in Fig. 57. An alternate circuit using an inexpensive NEC NE411 is shown in Fig. 58. The 3N204-type devices typically deliver 1.5- to 2.0-dB noise figures, while the NE411 typically delivers a 0.5- to 0.7-dB noise figure.

A low-pass type filter network was chosen for the input circuit to enhance rejection of the unwanted sideband (1152 MHz + 1296 MHz) generated by the doubly balanced mixer and to reflect any LO power coming out of the IF port. The input circuit should be adjusted for minimum noise figure, and the output network can be optimized for maximum gain. If a gain adjustment is desired, the voltage of gate 2 can be further decreased by making the 51-kΩ resistor variable.

For both the input and output PIN diode switches, bias current is limited to 50-60 mA by the 220-ohm resistor in the common-port leg of each switch. In addition, this produces 11 V at the cathode to reverse bias the "off" section diode. The 100-kΩ resistors allow leakage current to flow through the "off" diode. The reverse bias condition tends to increase the isolation in the "off" state by decreasing diode capacitance.

The TR IF switch is a good basic building block that can be applied to any VHF or UHF transverter design. It is best built in three separate enclosures — high-power IF switch and attenuator, low-power IF switch and IF preamplifier. Since the high-power

FB — Ferrite bead.

L1 — 6t no. 24 wire, 0.25 inch ID, spaced 1 wire dia.

L2 — 5t no. 24 wire, 0.25 inch ID, spaced 1 wire dia., tapped 1t from cold end.

Q1 — NEC NE41137 dual-gate GaAsFET.

RFC1 — 1- $\mu\text{H}$  miniature molded RF choke.

IF switch directs the 10-W signal from the 2-meter transceiver to R1, it is imperative that this section be enclosed in its own box

to prevent excessive radiation into the rest of the transverter. Keeping the sections separate also enhances the isolation abilities

of the PIN diode switches. See Fig. 59.

Use good VHF wiring practice when building the IF preamplifier. A good shield between the input and output is suggested, as well as a ferrite bead on gate 2 of the device to reduce tendency to oscillate. If stability is a problem under certain load conditions, decrease the value of the resistor in parallel with L2.

Fig. 59 — The high-power IF switch is fully shielded to prevent RF from entering other stages.

Fig. 62 — Approximate resonant frequency of the cavity filter for various degrees of screw penetration.

## 1296-MHz RF BAND-PASS FILTER

The primary function of the RF band-pass filter is to achieve adequate image rejection during receive and adequate unwanted sideband rejection during transmit. In both cases, the undesired product is 1152 MHz - 144 MHz = 1008 MHz. The simple quarter-wave filter described here achieves 28 dB of rejection at 1008 MHz while introducing only 0.4-dB loss at 1296 MHz. In addition, 20 dB of rejection is achieved at the 1152 MHz LO frequency. The complete frequency response is shown in Fig. 60. The 1-dB bandwidth is 18 MHz, while the 3-dB bandwidth is 40 MHz. SWR at resonance is 1.15:1.

Construction details are given in Fig. 61. Three of the four sides and the bottom of the filter are made from 1/16-inch-thick double-sided circuit board material. The inner dimensions of the cavity should be 0.75 inch square by 1.9 inches long. A piece of sheet brass covers the top of the cavity and also serves as a mounting point for the no. 6-32 brass screw.

A 1.8-inch length of 0.25-inch-diameter hobby brass tubing is centered on the cavity floor and aligned with the tuning screw. Make sure the tuning screw never makes contact with the brass tubing over the entire tuning range.

Connectors should be SMA type because of their small size. The author used SMA connectors with four small mounting tabs that soldered to the cavity inner wall. Whatever type SMA connectors you decide to use, make sure that the connector ground connection is made directly to the inner cavity wall; otherwise, RF performance will suffer. The capacitive probes that are soldered to the connector center conductors should be made out of thin sheet brass and formed as shown in Fig. 61. With the cavity assembled, adjust the spacing between the tab and center conductor to 0.050 inch.

After all components are assembled inside the cavity, install a piece of sheet brass over the front of the cavity to seal the unit. Press the sheet brass slightly into the cavity (about 0.020 inch) so it can be soldered directly to the inner cavity walls at the edges.

If additional out-of-band rejection is desired, two filters can be cascaded. Other

Fig. 61 — Construction details of the capacitively coupled cavity filter. See text for additional information.

Fig. 63 — Construction details of the inductively coupled cavity filter.

options are to decrease the size of the coupling capacitors and/or increase the impedance of the cavity from 70 ohms to about 100 ohms. Loss will increase slightly. Another option open to the builder is to build a multi-element interdigital filter as described by Fisher and Hinshaw<sup>1,2</sup>.

As an added feature, the filter can be used as a wavemeter to aid in tuning up local oscillators. Fig. 62 is a plot of resonant frequency versus depth of penetration of the no. 6-32 screw into the 0.250-inch diameter tubing. Positive numbers indicate penetration; 0 means flush; and negative numbers indicate distance from open end of tubing. With the tuning screw completely removed, the cavity will resonate at approximately 1375 MHz.

The first band-pass filter tried by the author was a scaled W1JR 432 MHz cavity filter using inductive coupling.<sup>3</sup> It does not offer the image rejection of the

capacitively coupled filter just described, but it does have a characteristic that may be advantageous to someone who operates at both 1296 and 1269 MHz. When adjusted for minimum loss (0.5 dB) at 1296 MHz, the insertion loss at 1269 MHz is only 3 dB. The capacitively coupled filter rolls off about 6 dB at 1269 MHz. The 1-dB bandwidth of the inductively coupled filter is 30 MHz, and the 3-dB bandwidth is 56 MHz. The image rejection at 1008 MHz is 18 dB, compared to 28 dB for the capacitively coupled design.

The inductively coupled filter construction is shown in Fig. 63. Construction and materials are very similar for both filters. The inductive loops are made from no. 20 enameled wire. The filter tunes to 1296 MHz when the tuning screw penetrates 0.28 inch into the brass-tubing resonator.

The filters just discussed represent the simplest designs that can be used effectively at 1296 MHz. They both offer adequate rejection of unwanted signals when used in conjunction with a doubly balanced mixer.

## SINGLE-POLE, DOUBLE-THROW RF SWITCH

At first glance, the requirement for a

low-loss, low-cost RF switch would seem to dictate that the switch be electro mechanical. But not so! Hewlett Packard manufactures a PIN diode, part number HP5082-3379, which has extremely low loss and is inexpensive (a couple of dollars each in small quantities). The circuit shown in Fig. 64 is a simple SPDT switch using a series diode in each leg. "Off" isolation is enhanced by using the positive voltage that is created across the 470-ohm resistor when either series diode is forward biased. The positive voltage reverse biases the opposite diode because reverse leakage current is allowed to flow through the 47-kΩ resistors. The RF switch has only 0.5 dB loss at 1296 MHz. The "off" port isolation at 1296 MHz has been measured at 21 dB.

Having additional isolation is not extremely important in this transverter design since only the receive or transmit section is powered up at any one time. The isolation as measured is adequate to eliminate loading effects on the normal

"through" port performance.

The circuit is laid out on a 1.2- × 2.0-inch, 0.062-inch-thick, double-sided, glass-epoxy circuit board. One side is un-etched and acts as a ground plane. Parts placement is shown in Fig. 65 and a photo of the finished unit is shown in Fig. 66. Transmission lines of 50 ohms (0.1 inch wide) enhance the high-frequency response. Holes 0.25 inch in diameter are drilled through the board to allow the PIN diode to be mounted with the leads flat on the circuit trace. C1, C2 and C3 can be either 0.05- or 0.1-inch square and are soldered directly to the circuit trace in the center of the line. SMA type connectors (2 or 4 hole flange mount) are recommended and should be soldered to the ground plane. In addition, run small screws, metal tabs or wire through the SMA connector holes and solder both sides to tie the top and bottom ground planes together.

### 1296-MHz PREAMPLIFIER

The simple preamplifier shown in Fig. 67 uses an inexpensive Hewlett Packard HXTR-3101 bipolar device. Noise figure is just under 2 dB with an associated gain of 12 dB. The preamp as described here will decrease the SSB mixer noise figure from 12 dB to 4 dB — a significant improvement in sensitivity!

### Circuit Design

The input match is accomplished with a conventional pi network that is tuned by C1 and C2 for best noise figure. The output match is accomplished by a high-pass L network that requires no tuning. The bias circuit is set up for  $V_{ce}$  of 10 V with an  $I_c$  of 10 mA to obtain the lowest possible noise figure. If necessary, the 7.5-kΩ base-bias resistor can be varied to obtain 10-mA idling current.

### Construction

The preamplifier is built in a 1 × 2 × 3-inch enclosure made from double-sided circuit-board stock. With the layout shown in Fig. 67, no shield between the input and output circuits should be required. Both Q1 emitter leads are soldered to the ground

plane with leads as short as possible. Connectors can be any convenient type — N, BNC or SMA.

The input microstripline is 0.25 inch wide. It is mounted 0.2 inch above the ground plane and suspended between C1 and C2. These piston trimmers are mounted on 0.75 inch centers. The actual length of L1 will be approximately 0.5 inch.

### LOW-POWER RF AMPLIFIER

After the IF signal is mixed up to 1296 MHz, filtered and passed through the RF switch, the power level, if all goes well, is in the region of -10 dBm. The requirement now exists for a stage that can amplify the -10 dBm (0.1 mW) signal up to +10 to +13 dBm (10 to 20 mW). Typically, many builders turn to the common MRF901 preamplifier circuits and operate them as small-signal class-A amplifiers. This is fine, but the circuits must be tuned by expensive piston trimmers and these are best reserved for higher power or preamplifier stages.

The two-stage amplifier shown in Fig. 68 requires no tuning and is unconditionally stable. It is built in a 1.2- × 2.0-inch enclosure. Compare this to the MRF901 stages which are typically 2 × 4 inches each, require tuning and are sometimes difficult to get running. The amplifier used here is designed around two silicon monolithic microwave integrated circuits (MMICs) manufactured by AvanteK. The first stage uses an MSA-0235-21, while the second stage is an MSA-0335-21. Inside each device is a Darlington-connected transistor pair that uses both series and shunt feedback to obtain broad-band gain usable to above 3 GHz. The devices used here are part of a series of ICs that are rated at different gain and power levels.

The MMICs have been optimized for use in a 50-ohm system. The input and output of each device are dc connected and require an external bias decoupling choke. The only other parts needed for a complete gain stage are a series current-limiting resistor and dc blocking capacitors. Compare this to the many associated parts needed for an MRF901 stage.

The bias circuitry was optimized for operation at 1296 MHz, although the two-stage amplifier is still quite usable at 2304 MHz:

Frequency	Gain	1-dB Compression Pt.
1296 MHz	24 dB	+13 dBm
2304 MHz	14 dB	+7 dBm

The amplifier circuit was etched on 0.062-inch-thick, double-sided, glass-epoxy

Fig. 69 — Parts placement diagram for the low-power MMIC board. A full-size etching pattern may be found at the back of this book.

circuit-board material. The etching pattern is a modified version of the SPDT switch design, except the center piece of 50-ohm microstripline was cut in the middle to accommodate C2. One side is unetched and acts as a ground plane. See Fig. 68. The etched board fits nicely into a Bud CU-123 diecast box. See Fig. 69.

The input and output connectors are 2- or 4-hole flange-type SMAs and are soldered to the unetched ground plane. On the ground-plane side, use an end mill or drill bit approximately 0.136 inch in diameter to remove the copper around the SMA center pin. This minimizes the discontinuity between the SMA connector and board by insuring that the 50-ohm impedance is maintained when they are mated. It is desirable to connect the top and bottom ground planes together at the connectors with screws or wire feed throughs that are soldered to each side.

Drill a 0.25-inch-diameter hole through the board to clear the body of each MMIC. Carefully bend the ground leads of each device downward through the hole and solder them to the unetched ground plane. Use a 1/32-inch-diameter lead as a tool to assist in bending the fragile leads. Do not bend directly at the case, or they may break off. Use care in soldering the chip capacitors and the devices to the board. A 15-W pencil-type soldering iron is sufficient. Excessive heat will only burn off what little metallization is available on the chip capacitors. Keep the RF chokes and current-limiting resistors away from the input side of the MMICs and away from each other to avoid problems with external undesired feedback.

Typical current drawn by each device is 50 mA, or 100 mA total for the two-stage amplifier. If you are so inclined to run this amplifier as a preamplifier, the noise

Table 8

#### Cascaded MMIC Performance

Lineup (MSA-####)	$P_{out}$ @ 1 dB C.P. (dBm)	Gain @ Low Level (dB)	$P_{in}$ @ 1 dB C.P. (dBm)
0235-0335	+ 12	25	- 13
0204-0304	+ 10	20	- 10
0304-0404	+ 13	16	- 3
0204-0304-0404	+ 13	25	- 12

figures at 1296 MHz and 2304 MHz are typically 4.7 dB and 5.3 dB, respectively.

The current-limiting resistors suggested in Table 7 should be used as a guide when initially setting up the MMICs. The values should be adjusted accordingly to draw the desired current. No tune-up is required!

Avantek has recently released an entire

line of plastic package equivalents to the "micro-x" package devices shown here. Typical 1300-MHz performance for both package styles is shown in Table 7. Several suggested device line ups are characterized in Table 8. Probably the best approach for the money is the 0204/0304/0404 line up. The 1-dB compression point is good, and

gain is high enough that additional mixer and or filter loss could be tolerated if required.

#### 80-mW AMPLIFIER

The amplifier stage described here is capable of producing greater than 100 mW of output power. The 1-dB compression

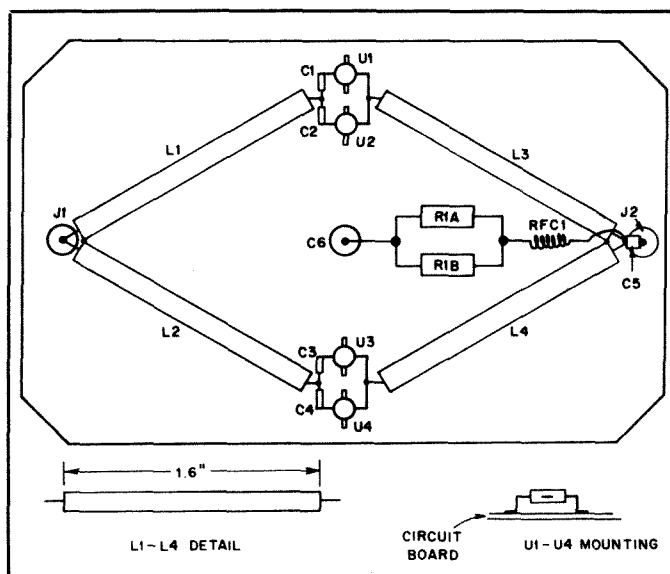

Fig. 71 — Parts placement diagram for the 80-mW amplifier using four MSA-0404 MMICs.

point is 80 mW (+19 dBm). The schematic diagram is given in Fig. 70. Gain has been measured at 5.5 to 6.0 dB in its linear operating range. This amplifier requires no tuning whatsoever. Apply 12- to 13.5-V dc and RF drive, and that's it.

### Circuit Details

The heart of the amplifier is the Avantek MSA-0404 MMIC with usable gain from dc through 3 GHz. This design uses four of these devices. Two 0404s are connected in parallel, and then the two parallel-connected pairs are combined with Wilkinson power dividers on the input and output. Because they are connected in parallel, the input and output impedance of each pair of 0404s is 25 ohms. The 25-ohm impedances are transformed up to 100 ohms through quarter-wavelength sections of 50-ohm coaxial cable. At the input and output connectors, the 100-ohm impedances from each pair are paralleled to obtain the desired 50 ohms for the input and output. Blocking capacitors are used on the input to each MMIC for dc isolation. The outputs of each circuit are paralleled for dc, and bias is applied through one common series bias resistor and RFC.

### Construction

The amplifier is built on a 2.05- × 4.05-inch piece of 0.062-inch-thick, glass-epoxy, double-sided circuit board. This board installs nicely into an aluminum diecast box (Bud CU-124, Hammond 1490B). Recommended component layout is shown in Fig. 71. SMA connectors are suggested. The transmission lines are made from miniature 50-ohm semi-rigid coaxial cable (UT-141 or equiv.). Cut each piece so that the outer jacket is 1.6 inches end-to-end. All four cables should be carefully cut to the same length within ±0.20 inch. This is a little over ±1 electrical degree at 1296 MHz. Tack solder the outer jacket of each piece of semi-rigid cable to the ground plane at the end of each line.

Be very careful when handling the MMICs; the leads may break off if they are bent directly at the case. Use the lead from a 1-W resistor as a tool to form the leads of each device as shown in Fig. 71. Use a 15-W soldering iron to tack solder the ground leads to the ground plane and solder to the input and output leads. Mount the devices so that the center-to-center distance is 5/16 inch maximum. This way, the 0.1- × 0.1-inch chip capacitors can be mounted between the semi-rigid center conductor and the device input. A very short length of no. 24 wire can be used to tie the MMIC outputs and the semi-rigid center conductor together. When laying out the semi-rigid coax be sure to leave enough room near the output connector for C5. See Fig. 72.

### NE41620 AMPLIFIER

The NE41620 is a rugged stud-mount device that will deliver 250 mW at the 1-dB

Fig. 72 — The 80-mW amplifier fits inside a standard Bud or Hammond diecast box.

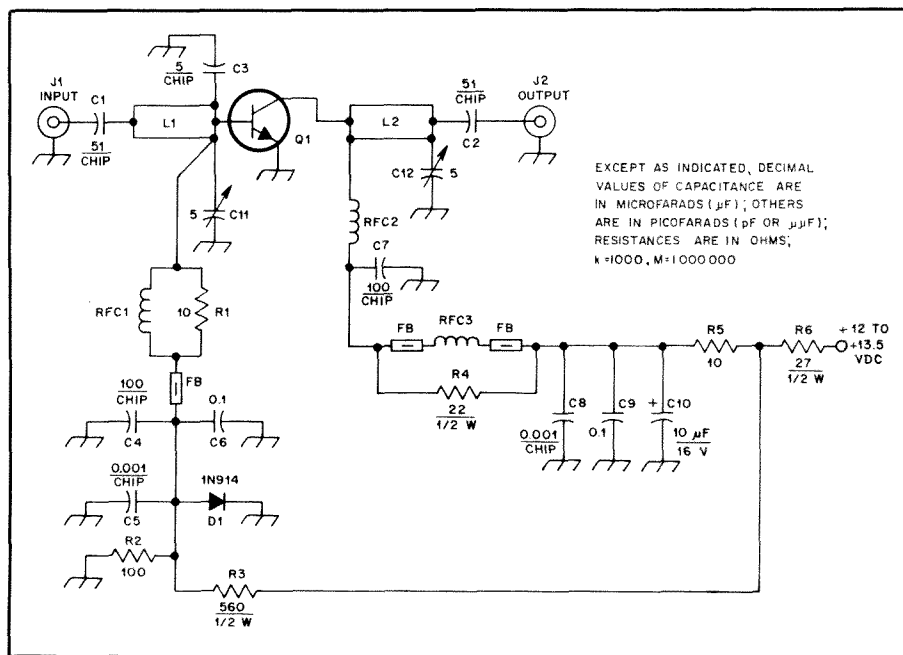

Fig. 73 — Schematic diagram of the NE41620 power amplifier. Resistors are 1/4-W carbon-composition types unless noted.

- C3 — 5-pF chip capacitor.
- C4, C7 — 100-pF chip capacitor.
- C5, C8 — 1000-pF chip capacitor.
- C6, C9 — 0.1-μF disc-ceramic capacitor.
- C10 — 10-μF electrolytic capacitor.
- C11, C12 — 5-pF variable capacitor.
- D1 — 1N4001 or 1N914.
- FB — Ferrite bead.
- L1 — 27-Ω microstripline, 1/4 wavelength long. See text.

- L2 — 51-Ω microstripline, 1/4 wavelength long. See text.
- Q1 — NEC NE41620 power transistor.
- RFC1 — 4t no. 24 enam. wire, 0.125 inch ID, 0.375 inch long.
- RFC2 — 3t no. 24 enam. wire, 0.125 inch ID, 0.25 inch long.
- RFC3 — 1-μH RF choke; 18t no. 24 enam. wire close spaced on Amidon T50-10 toroid core.

compression point when used in the circuit shown in Fig. 73. Gain is 8 to 10 dB at 200-mW output, so the +13-dBm power level available from the low-level MSA-204/0304/0404 driver is just right.

### Design and Construction

This circuit uses L networks for input and output matching. The series elements are microstriplines. The characteristic impedance of the input line is 27 ohms, and the output is 51 ohms. The shunt matching elements are variable capacitors C11 and C12; they can be either miniature piston

trimmers or PC-board mount parallel-plate trimmers. Solder C3 directly across the Q1 base and emitter leads.

Q1 idling current is set by a bias network consisting of R2, R3 and D1. RFC1 and RFC2 were chosen for optimum RF decoupling performance at 1296 MHz, while RFC3 and R4 were chosen to reduce the transistor's ability to generate low-frequency spurious signals. C4 and C7 provide a good bypass at the frequency of operation, and the remaining bypass capacitors provide a low-impedance path to ground for lower frequencies.

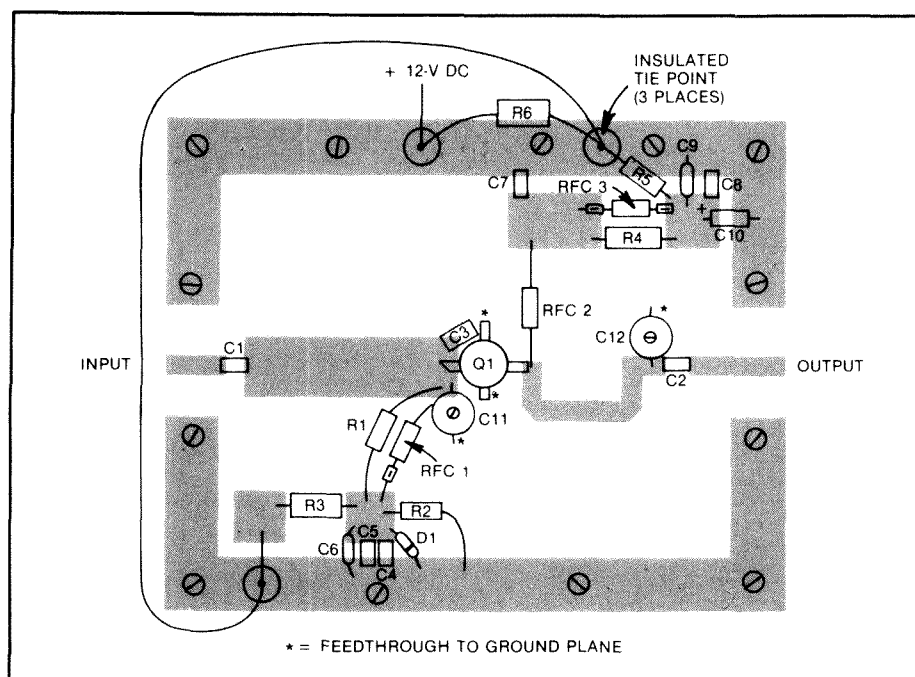

Fig. 74 — Parts placement diagram for the NE41620 amplifier. A full-size etching pattern appears at the back of this book.

Fig. 75 — The NE41620 amplifier is mounted to an aluminum block and the RF connectors are mounted to the ends of the block.

The NE41620 amplifier is built on a double-sided, 0.062-inch-thick, glass-epoxy PC board. Parts placement is shown in Fig. 74. One side of the board is left unetched to act as a ground plane. The PC board is mounted on a 0.25-inch-thick aluminum block to facilitate the mounting of four-hole flange-type SMA connectors for the RF input and output. If desired, the amplifier can be mounted in a suitable enclosure and coaxial cable can be run between the circuit board and RF connectors. Type-N or BNC connectors could also be

used. Be sure to use screws to tie the top ground plane to the bottom ground plane and aluminum plate, as shown in Fig. 74. This is especially important near the critical bypass areas. Additional details may be seen in Fig. 75.

#### Tune-up

For initial tune-up, start with C11 and C12 at minimum capacitance and connect 50-ohm loads to both the input and output. Slowly apply 12 to 14 V and monitor the collector current through R5. Idling

current should be approximately 20 mA. If adjustment is necessary, change the value of R3 accordingly (that is, increase the resistance value to decrease collector idling current). It has been observed with various devices that R3 may need to be as high as 1000 ohms to keep idling collector current at 20 mA. This is normal.

Apply 10-mW drive and tune C11 and C12 for maximum power output. The output power should be 70 to 100 mW. Increase drive and readjust C11 and C12 so the output power achieved is 200 mW. Collector current should be approximately 70 mA. Saturated power output has been measured at 300 mW. The measured 1-dB compression point of the amplifier is 250 mW, but it is suggested that the amplifier be run at the 200-mW level.

Do not omit R5 and R6 in an attempt to attain greater power output; collector current will be excessive. Do not exceed the absolute maximum collector current rating of 100 mA as suggested by the manufacturer. R5 also provides a convenient point at which to monitor collector current.

#### TR SEQUENCER

The need for a sequencing circuit to control TR switching became rather obvious after an IF amplifier was blown out by excessive RF from the 2-meter rig. When the transverter was used for SSB operation, RF was available at the IF TR switch before it had completely switched to the transmit circuits. This RF could potentially destroy RF preamplifiers and coaxial TR relays. The situation is even further compounded during FM operation since a carrier is sent to the transverter at the same time the coaxial switch and the IF and RF PIN-diode switches are in the process of switching.

The desired sequence of events when going from receive to transmit is as follows:

- 1) Transverter receive section turns off.
- 2) Transverter TR relay transfers to the transmit state.
- 3) Transverter transmitter stages turn on.
- 4) Power amplifier turns on, or feedback to IF transceiver to turn on power stage.

Conversely, when going from transmit to receive, the opposite sequence is desired:

- 1) Power amplifier turns off, or IF transceiver power stages turn off.
- 2) Transverter transmitter stages turn off.
- 3) Transverter TR relay transfers to receive state.
- 4) Transverter receive section turns on.

The circuit shown in Fig. 76 fulfills all of these requirements.

The sequencing circuit used here was inspired by work done by Chip Angle, N6CA. The N6CA version is presented as a stand-alone project in Chapter 31. The circuit shown here uses an inexpensive LM324 quad op-amp. Each section is used as a differential amplifier. A string of resistors produces a progressively higher

C1 — 20-μF electrolytic (see text).

D1, D2 — 1N914 or equiv.

Q1-Q5, Q7, Q9 — 2N2222A or equiv. (RS 276-2009).

Q6 — 2N2907 or equiv. (RS 276-2023).

Q8, Q10 — TIP32 or equiv. (RS 276-2027).

U1 — LM324 quad op-amp.

reference level on each section. The RC circuit (R4, C1) controls the timing and the voltage applied to the + input of each section.

The sequencer is set up for two input options. The A input is set up for the ground-to-transmit mode and can be paralleled with the microphone PTT on most 2 meter multi-mode radios. Input B is activated by applying 9- to 12-V dc. Since an isolation diode is used in series with port A input, an extra control diode is used in the emitter lead to ensure that Q2 can be turned off so point C can go high to charge the R4/C1 combination.

As the R4/C1 charges, each op-amp turns on in sequence, causing points D through G to sequence on. When point D goes high (12.5 V), Q3 turns on, causing Q4 to turn off; this turns off the receive section. When point E goes high (12.5 V), Q5 turns on, causing Q6 to turn on; this triggers the coaxial TR relay. In a similar fashion, the bias circuits on the transmit power stages are turned on via Q7 and Q8. Q9 and Q10 can be used to turn on an ex-

ternal driver/final amplifier, or this switch can be used to turn on the IF transceiver transmit stages if desired.

When the PTT switch is opened to return to the receive mode, point C returns low. This causes C1 to discharge through R4, Q2 and D2. Each of the op-amps turns off in sequence. This turns off the load connected to Q10, then the transmit section, and finally the receiver circuits are turned on. The value of C1 can be set up for any charging/discharging rate. With 20 μF, the transverter sequences in less than several hundred milliseconds. The gain of the op-amps is reduced to an acceptable level by means of feedback resistors R14 through R17. This reduces the susceptibility to noise and RF. The 10-kΩ series resistors (R18 through R21) also help minimize RF susceptibility of the unit. Q3, Q5, Q7 and Q9 are buffer stages which minimize the current drawn from the LM324.

When a 2N2222 is used at Q4, 200 to 300 mA can be drawn in the receive mode. A heat sink is recommended. A 2N2907 at

Q6 allows up to 300 mA to be pulled safely. This should be adequate for most coaxial relays. If TIP32s are used at Q8 and Q10, 2 A can be pulled safely from each device. Q8 can be used to switch on all of the transmit circuits previously discussed. If higher powered amplifier stages are installed, it is suggested that  $V_{cc}$  be applied to each power stage at all times. Use Q8 and Q10 to apply bias for transmit. Otherwise the current-handling requirement of Q8 and Q10 would have to increase significantly.

## FINDING PARTS

Many small parts, such as resistors and capacitors, are available from the suppliers listed in Chapter 35. Applied Invention and Microwave Components of Michigan are sources of piston trimmer capacitors, chip capacitors, feedthrough capacitors and other related components. NEC transistors are available from California Eastern Laboratories, 3260 Jay St., Santa Clara, CA 95050. Avantek MMICs are available from stocking distributors around the

country. Contact Avantek, 3175 Bowers Ave., Santa Clara, CA 95051 for the name of the nearest distributor. Hewlett Packard devices are available from three major distributors that have offices around the country: Hall-Mark, Hamilton Avnet and Schweber. If you have trouble locating an HP distributor, call the sales office nearest you and ask an engineer in the electronic components group to steer you in the right direction. Microwave Associates parts are

available through Zeus in Port Chester, New York (tel. 914-937-7400) or Anaheim, California (tel. 714-632-6880).

## CONCLUSION

It is hoped that the ideas and concepts presented here will inspire you to build your own 1296-MHz transverter. With the availability of state-of-the-art MMIC amplifiers, a lot of work has been minimized. These

ideas can be adapted to different designs. Modular design makes it easy to pick and choose the stages you need.

The author wishes to thank his wife Emily, K5DOI, KN5N, WB5AFY, WA5TKU, W5ETG, WA5VJB and K5GW for their assistance in bringing this project to fruition. Microwave Associates, Hewlett Packard, California Eastern Laboratories, Avantek and Tele-Tech provided components.

# 1296-MHz Solid-State Power Amplifiers

With the ever-increasing number of commercial 1296 MHz transverters available on the market today, there exists an even greater demand for a simple and economical way to generate higher power. Most of the transverters presently available produce 0.5 to 1 watt of output. If this power level is used to drive a typical 2C39/7289 strip-line or cavity amplifiers, the low power output is often disappointing. If the tube-type amplifier is run with at least 1 kV on the plate, typical gain is around 10 dB. This means that the 0.5 to 1 W is now at best 5 to 10 W output. One alternative is to cascade two of these amplifiers. We now could expect 50 to 100 W of output power.

This section describes two solid-state amplifiers that can replace the 2C39/7289 as the driver and provide 10-20 W — enough to drive a two-tube amplifier to full output. These amplifiers, shown in Figs. 77 through 81 were designed and built by Al Ward, WB5LUA.

The NEC NEL1306 and the NEL1320 were recently introduced as an economical solid state approach to generating moderate power (10-20 W) at 1269 and 1296 MHz. These amplifiers can be used for terrestrial or satellite work. When OSCAR 10 was designed, it was thought that 10 W into a modest gain antenna (20 dBi) would pro-

duce usable signals from the satellite. Unfortunately, there were some problems and the sensitivity of AO-10 was not as originally expected for the Mode L uplink. These amplifiers can, however, be used as a driver for a higher-powered tube amplifier for Mode L service. If all goes according to plan, with the launch of AMSAT-OSCAR Phase IIIC in mid 1986, 10 to 20 W with a 20-dBi gain antenna will produce acceptable downlink signals.

The NEL1306 is rated for 6-W output at 1296 MHz at the 1-dB compression point; the NEL1320 is rated at 20 W. One of the advantages of these devices is that they were designed for a  $V_{cc}$  of 12- to 13.6-V dc, making them ideal for portable and mobile operation. The NEL1306 is in the \$26 price range, while the NEL1320 costs about \$42. These are single-quantity prices, making the devices attractive to experimenters.

The performance of these amplifiers as built and tested by the author is shown in Table 9. The NEL1306 is a good buy. With 1.5 W input, 8 W output can be achieved. When tuned up at lower power levels, power gain can be as high as 10 dB. With 0.2 W drive from the transverter described earlier in this chapter, an output power level of 2.0 W is obtainable.

Table 9

Typical Operating Conditions for the 1296-MHz Solid-State Power Amplifiers

Device	NEL130681-12	NEL132081-12
$P_{out}$ (1-dB C.P.)	7 W	18 W
Gain (1-dB C.P.)	6 dB typ.	5 dB typ.
Collector efficiency	40-50%	40-50%
Idling current	50 mA	150 mA
$I_c$ @ 1-dB C.P.	1.1 A	3.0 A
$V_{cc}$	13.5 V	13.5 V
Power input	14.9 W	40.5 W

Power gains as high as 17 dB are possible with a two-stage amplifier (an NEL1306 driving an NEL1320). With a mere 200 mW of drive, 10-W output can be obtained. When driven with 1 W, the 1-dB compression point of 18 W will be achieved.

## Circuit Details

The basic design, shown schematically in Fig. 77, is an adaption of a circuit described in the NEL1300 series data sheet. The design incorporates 30-ohm quarter-wavelength microstriplines on both the input and output. Shunt capacitors C3, C4, C7 and C8 form a pi network designed to match the low input impedance of the

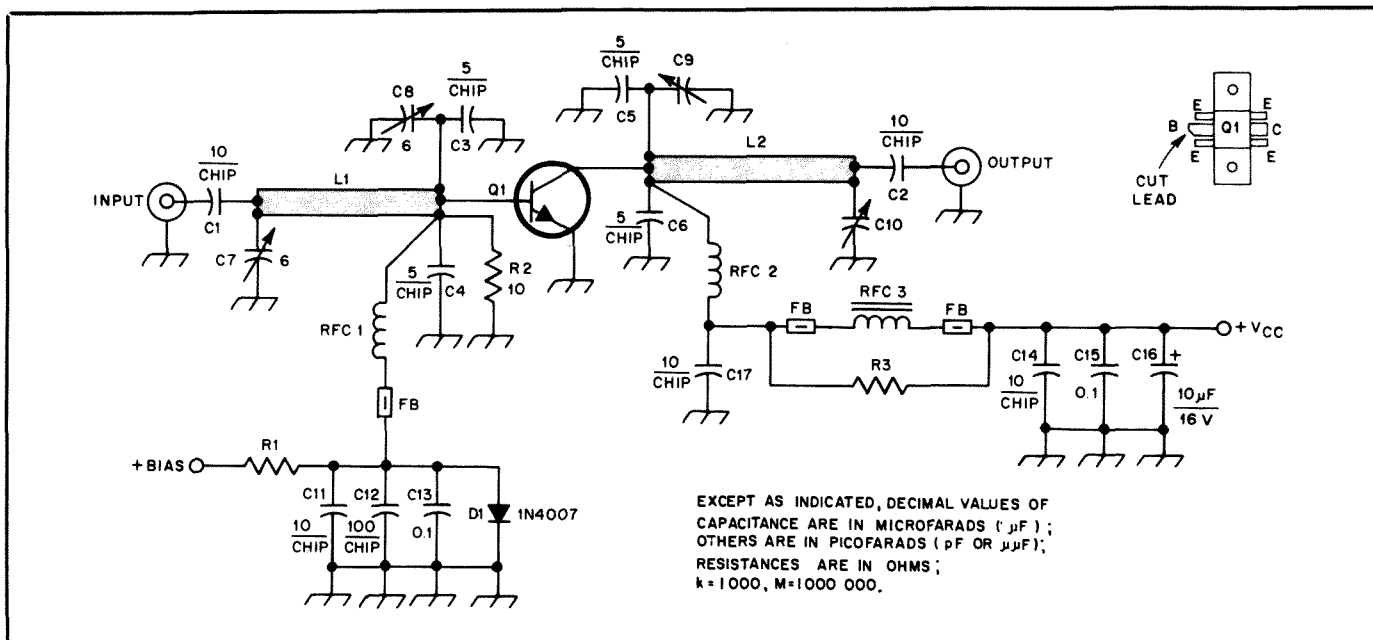

Fig. 77 — Schematic diagram of the NEL1306 and NEL1320 1296-MHz solid-state power amplifiers. The schematic is identical for both versions. Component values are the same except as noted.

C1, C2, C11, C17 — 10-pF chip capacitor.  
 C3, C4, C5, C6 — 3.6- to 5.0-pF chip capacitor.  
 C7, C8 — 1.8- to 6.0-pF miniature trimmer capacitor (Mouser 24AA070 or equiv.).  
 C9, C10 — Same as C7 and C8 for the NEL1306 amplifier. For the NEL1320 version, 0.8- to 10-pF piston trimmers are used (Johanson 5221 or 8053 or equiv.).  
 C12, C14 — 100-pF chip capacitor.

C13, C15 — 0.1-μF disc ceramic capacitor.  
 C16 — 10-μF electrolytic capacitor.  
 D1 — 1N4007 diode.  
 L1, L2 — 30-ohm microstripline, ¼ wavelength long (see text).  
 Q1 — NEC NEL130681-12 (6 W) or NEL132081-12 (18 W) transistor.  
 R1 — 82- to 100-Ω resistor, 2-W minimum. Vary for specified idling current.

R2 — 10-Ω, ¼-W carbon-composition resistor with "zero" lead length. See text.  
 R3 — 15-Ω, 1-W carbon-composition resistor.  
 RFC1 — 3t no. 24 wire, 0.125 inch ID, spaced 1 wire dia.  
 RFC2 — 1t no. 24 wire, 0.125 inch ID, spaced 1 wire dia.  
 RFC3 — 1-μH RF choke; 18t no. 24 enam. close-spaced on a T50-10 toroid core.

device to 50 ohms. C5, C6, C9 and C10 and the 30-ohm transmission line form an output pi network that matches the device to 50 ohms. C10 is not always necessary, depending on variations among devices and PC-board material. Glass-epoxy circuit-board material 0.031 inch thick was chosen for the dielectric material. A 30-ohm line in this dielectric equates to a line width of 0.121 inches, which is equivalent to the width of both the collector and base leads of the NEL1300 series devices. This minimizes the discontinuity among L1, L2 and Q1.

Bias is provided by R1, R2 and D1. R1 can be optimized, if desired, to adjust the collector idling current.

RFC1 and RFC2 were selected by choosing the lowest possible reactance that will not affect power gain or output power. The RF chokes and the 10-pF bypass capacitors afford adequate decoupling at the frequency of operation. The values of RFC1 and RFC2 were purposely made different to avoid oscillations caused by bias choke coupling.

Keeping the high-frequency RF chokes in the collector as small as possible allows the parallel R3/RFC3 combination, in conjunction with bypass capacitors C14, C15, C16, to reduce the tendency of the transistor to generate low-frequency spurious signals. The 1-μH RF choke must be capable of handling 1 A for the NEL1306 and 3 A for the NEL1320. Special RF

Fig. 78 — Parts-placement diagram for the solid-state 1296-MHz power amplifiers. The same PC boards are used for each version. A full-size etching pattern may be found at the back of this book.

Fig. 79 — Construction details for the solid-state 1296-MHz power amplifiers. See text for additional information.

Fig. 80 — This NEL1306 amplifier was built inside a diecast box. Miniature coaxial cable runs to the connectors.

Fig. 81 — The NEL1320 amplifier is virtually identical to the NEL1306 version, except for the capacitors on the output stripline. C10 was not necessary on this version.

chokes were built to withstand the current.

### Construction

The circuit is etched on 0.031-inch thick, double-sided, glass-epoxy circuit board. The layout is given in Fig. 78. Two separate boards are actually used — one for the input side and one for the output — and they are mirror images of each other. The copper is retained on the bottom side and serves as the ground plane. In addition, the grounded areas on the top side must be held at RF ground. This insures low-inductance grounding for the transistor emitter leads, matching capacitors and bias circuitry.

Several effective methods of grounding of the top ground plane to the bottom ground plane are summarized here.

- 1) Plated-through holes at the critical grounding areas mentioned above.

- 2) Use of pins or screws that penetrate through the circuit board and into the aluminum base plate at the critical areas.

- 3) Use of "wrap-around" foils on all edges of the ground plane.

Plated-through holes are often used in the commercial and military electronic marketplace but are not so easily reproduced in the average builder's circuit-board shop. The best technique is to use the "wrap-around" foils on all edges and use no. 4-40 screws to tie the circuit board to the base plate at the critical areas shown in Fig. 78. Solder the brass or copper foil to both ground planes.

It will be necessary to mill out a 0.240-inch-wide slot in the aluminum base plate to allow the transistor flange to be mounted 0.090 inch below the main surface, or to build up the input and output printed circuit boards with a 0.090-inch-thick aluminum plate. This is required since the transistor leads protrude from the device 0.165 inch above the bottom of the flange, and the PC boards are only 0.031 inch high. These dimensions allow a wrap-around foil and solder buildup of 0.040 inch maximum.

One-inch screws are used to hold the

transistor to the aluminum base plate. The base plate was drilled and tapped to accept the screws. The extra screw length that protrudes from the bottom of the base plate allows the use of an external heat sink, which is highly suggested if continuous operation is desired.

The clearance holes in the NEL1300 devices are for no. 4-40 hardware. The holes were drilled out to accept no. 6-32 screws to make the assembly more rugged, although this may not be necessary. Be careful if you decide to drill out the holes to accept no. 6-32 hardware: the base plate is soft copper, and you could damage the device. Use a small vise to hold the transistor flange during the drilling operation.

The transistor leads should be soldered in place only after the circuit boards and transistor have been firmly bolted down to the base plate. This is necessary to minimize any buildup of stress in the transistor leads. Chip capacitors C3, C4, C5 and C6 should be soldered directly onto the leads of Q1 to ensure the shortest possible lead length.

In the original design of these amplifiers, Johanson piston trimmer capacitors (part no. 5221 or 8053) were used for C7, C8, C9 and C10. These capacitors are fairly large, and in some instances the coupling between the bodies of C8 and C9 was enough to cause an in-band oscillation. Smaller variable capacitors should be used if at all possible. Mouser Electronics (see Chapter 35) part number 24A070, a 1.8- to 6.0-pF miniature trimmer capacitor, has been used successfully in the input and output networks of the NEL1306 with no performance degradation. The Johanson piston trimmers were used in the output network of the NEL1320 amplifier because of the high RF currents involved.

The original printed circuit board was designed to allow end-launch SMA-type connectors to be installed. Fig. 79 illustrates this technique. Four-hole, flange-mount SMA connectors can be mounted to the edge of the 0.250-inch-thick base plate using two of the four mounting holes. Drill

and tap the base plate for no. 2-56 hardware. Extreme care must be exercised — it's easy to accidentally cross-thread or over-torque the no. 2-56 hardware.

An alternative approach is to mount the amplifier in an aluminum diecast box (Bud CU-124 or Hammond 1590B) and run miniature 50-ohm coaxial cable such as RG-174 from the amplifier board to the connector. The amplifiers shown in Figs. 80 and 81 use the standard SMA connectors mounted to the walls of the metal box. BNC or Type-N connectors should work equally as well. When preparing each end of the coaxial cable, try to keep the pigtail leads as short as possible (1/8 inch or less); otherwise the mismatch will be difficult to tune out.

A performance comparison was made on one amplifier with end-launch connectors and another using the approach just described. No difference in gain or 1-dB compression point could be measured. Etched PC boards and parts kits are available from A + A Engineering.<sup>3</sup>

### Tune-up and Operation

Initial setup of each amplifier is begun by terminating the input and output in good 50-ohm loads. Start with all capacitors at their minimum value. Apply 12- to 13.5-V dc to the  $V_{cc}$  and bias terminals. The collector idling current should be as shown in Table 9. R1 can be varied as required to obtain the correct idling current. For initial tuneup, it is suggested that a fuse be used in the collector lead to protect the device.

Measuring RF output power at this frequency can be difficult. The author used a calibrated 20-dB directional coupler along with enough attenuator pads to allow power to be read with a Hewlett Packard HP430C power meter and an HP477B thermistor mount. The HP431 power meter with its associated HP478A thermistor mount is a newer version of the HP430C and does not suffer from temperature drift problems. Bird offers several low-power

slugs for the popular model 43 in this frequency range. The 400-1000 MHz slugs can be used with decreased accuracy.

For the NEL1306 amplifier, start out with 50 to 100 mW of drive. Adjust the output network for maximum power output and then peak the input network for output power. Increase drive and repeak both matching networks for rated performance as shown in Table 9. Similarly, start out with approximately 1 W of drive for the NEL1320 and follow the same procedure. After a minute or two of operation at maximum power output, remove RF drive power and check to see that the collector idling current has not increased more than 25% over the initial setting. Keep D1 close to Q1. Thermal compound will enhance heat transfer to D1 to insure minimal drift in idling current with temperature changes.

Considerable effort was put forth to make sure that the amplifiers are stable. The devices have fairly high gain at the frequency of operation, so layout and good construction practices are very important. Here are some construction hints that can help ensure amplifier performance and stability.

1) Use the smallest (physical) size vari-

able capacitors that will still handle the RF current.

2) Use wrap-around ground foils as noted. Grounding screws are required at the critical RF ground areas near the shunt variable capacitors, shunt bypass capacitors and Q1 emitters.

3) Connect braids from the coaxial cable jumpers to same ground as the shunt variable capacitors.

4) Use as little lead length as possible on R2 — less than 0.125 inch.

5) In some instances where the large piston trimmers are used, a shield approximately 0.75 inch high mounted on top of Q1 and grounded via the mounting screws can improve isolation between C8 and C9.

If transistor switching is being considered as a method of applying dc power to the power amplifier stages during transmit, the following technique is recommended. Keep 13.5-V dc applied to the  $V_{cc}$  terminal during receive and transmit. Use a series transistor switch to apply 12- to 13.5-V dc to the bias terminal during transmit. A power transistor capable of carrying only a few hundred milliamperes of bias current, as opposed to several amperes of collector current, will be required. More important,

the voltage drop across the transistor switch in the  $V_{cc}$  line will be eliminated. This will ensure maximum power output of the NEL1300 devices by keeping  $V_{cc}$  at 13.5-V dc.

Several amplifiers of this design are currently in use. The NEL1300 series amplifiers offer a simple and efficient means of generating medium power on 1296 MHz. The 13.5-V dc requirement makes them ideal for mobile and portable operation.

Parts for this project are available from Applied Invention, Microwave Components of Michigan and Mouser Electronics (see Chapter 35). NEC transistors are available from California Eastern Laboratories, 3260 Jay St., Santa Clara, CA 95050.

The author wishes to thank everyone who offered technical advice, especially WASTKU for helping with the construction and evaluation of the prototype amplifiers.

# A Quarter Kilowatt 23-cm Amplifier

The amplifier project described here and shown in Figs. 99 through 123 offers the following features.

- 1) Covers 1240 to 1300 MHz.
- 2) Linear operation.
- 3) Grounded grid 7289/2C39 cavity amplifier, single tube.
- 4) Power gain ranges from 12 dB to 20 dB depending on output power, input power, loading, anode voltage and grid voltage.
- 5) 50-ohm input and output — no stub tuner required.
- 6) Power output greater than 200 W with about 12-W drive.

This project was designed and built by Chip Angle, N6CA. It was originally presented in March and April 1985 *QST*. All of the information given in the original article is reproduced here, including details of the design and construction of the RF deck and power supply, a practical water cooling system, testing and operation. The amplifier described here is a tried and proven design. It works well, is reliable and can be duplicated.

## General Design Approach

A cavity amplifier is similar to a conventional amplifier designed for lower frequencies. The tube anode excites a resonant circuit, and power is in turn coupled into a load, usually 50 ohms. Instead of using coils and capacitors, as at lower frequencies, the cavity provides the resonant circuit necessary to tune the amplifier output.

The anode cavity of this amplifier is a squat cylinder. Cylinder height is set by mechanical tube requirements. The inside diameter of the cylinder sets the highest resonant frequency. Any capacitance added from the top to the bottom of the cavity will lower its resonant frequency, as will increasing the cavity diameter.

This amplifier uses 1/8-inch-thick copper plates for the cavity top and bottom and a thick-wall aluminum ring, cut from tubing, for the walls. This heavy construction virtually eliminates all resonant frequency variations caused by thermal and mechanical changes.

Fig. 100 is the schematic diagram of the cavity amplifier. The circuit is simple. Filament voltage enters the RF deck through C4, C5, RFC1 and RFC2. High voltage is fed to the anode through RFC3. C8, the anode bypass capacitor, is homemade from Teflon® dielectric sandwiched between a copper plate and the chassis.

The input pi network easily tunes the entire band at any power level. It is made from two Johanson piston trimmer capacitors and a "coil" made from copper wire. An input cavity is not necessary at 23 cm.

Output coupling is through a rotatable loop that serves as a variable loading control. This allows amplifier-tuning flexibility; it may be tuned for maximum gain

Fig. 99 — The completed 23-cm amplifier.

or for maximum power. Light loading can produce stable power gains of up to 20 dB.

Amplifier tuning is accomplished with a homemade cylindrical coaxial capacitor with Teflon dielectric (C6). There are no moving metal parts to cause erratic performance. The Teflon rod/tube screws in and out of the coaxial capacitor, increasing or decreasing the capacitance by changing the amount of Teflon dielectric inside the cylinder. With the rod all the way in, the dielectric is all Teflon; with the rod all the way out, the dielectric is all air.

Teflon has a relative dielectric constant (relative to air = 1) of 2.05, which means that the value of the capacitor with the Teflon rod all the way in is twice the value of the capacitor with the rod all the way out. Full capacitance will pull the resonant frequency of the amplifier down to 1240 MHz. Use of only one anode tuning adjustment means the amplifier will have more gain because shunt capacitance has been minimized.

## Thermal Considerations

The cavity walls are formed by a thick-wall aluminum ring, which is sandwiched between two thick copper plates. RF and thermal properties of these two metals are reasonably close, whereas brass is rather poor in both respects. The 7289/2C39 tube used in this amplifier is being run at 2 to 2½ times its normal dissipation rating; therefore it's important to have a cavity that remains thermally stable.

Most previously described amplifiers

have used sheet brass in their construction. This has usually meant constant retuning of resonance to maintain output power at or near maximum.

The copper and aluminum construction in this amplifier has solved all thermal stability problems. The amplifier can easily be run key down for over an hour at 200-W output without retuning. This, of course, is obtained only with a good tube and water cooling.

Water cooling keeps the internal structure of the tube thermally stable. When air cooling is used for output levels of 100 to 150 W, output power fluctuations are a direct result of internal tube changes. These changes vary from tube to tube and must be tested for. In some cases, perfectly good RF tubes have had poor thermal stability. Such tubes can make good drivers at lower power levels.

## Construction

Hand tools are great if you are skilled and patient. Most people want to hurry up and finish their new project. If that's you, then have a machine shop make all of the parts, leaving only the final assembly up to you. It should cost you about \$200. The parts are not difficult to fabricate, but the process is time consuming. If you have the time and patience to do it yourself, this amplifier can be very inexpensive.

## Gathering the Materials

All of the materials used in this amplifier are fairly common and should be available

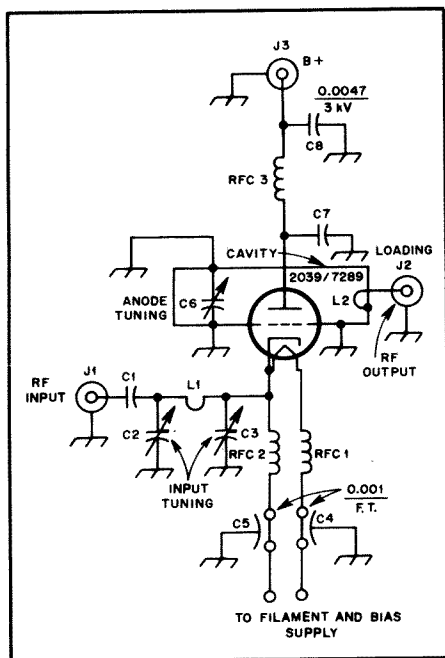

Fig. 100 — Schematic diagram of the 23-cm amplifier.

- C1 — 3-pF dipped mica capacitor.  
 C2, C3 — 1- to 10-pF piston trimmer capacitor (Johanson no. 3957, 5201 or equiv.).  
 C6 — Anode-tuning capacitor. See text and Fig. 110.  
 C7 — Anode-bypass capacitor, 90 pF. Homemade from copper plate and Teflon sheet.  
 C8 — Disc ceramic, 0.0047- $\mu$ F, 3-kV capacitor.  
 J1 — 5-mm SMA connector, chassis mount, female.  
 J2 — Modified Type-N connector. See text and Fig. 106.  
 J3 — Female chassis-mount BNC connector.  
 L1 — Loop of no. 18 bus wire soldered between C2 and C3. See Fig. 114.  
 L2 — Output-coupling loop. Part of output-connector assembly. See text and Fig. 106.

 RFC3 — 3t no. 20 tinned wound on a 20-ohm, 1-W carbon-composition resistor.

from suppliers in most metropolitan areas. Some suppliers have "short sale" racks where they sell odd pieces cut off standard lengths or sheets at reduced prices. The parts for this project are small enough that they may be fashioned from cutoff stock. Surplus-metal houses have some great buys, so start there if one is nearby.

The key to successfully completing this project is careful layout work before cutting or drilling any parts. Invest in a can of marking dye, a sharp scribe, an accurate rule, vernier calipers and several center punches. These tools are available at any machinists' supply shop. The marking dye will make cutting and filing lines much easier to see. Measure all dimensions as carefully as you can and then recheck them before cutting. Mark with a sharp scribe because the sharper the scribe, the finer the marked line, and the finer the marked line, the closer your cut will be to where it should be. Remember — the accuracy of your

Fig. 101 — Complete dimensions for the aluminum template.

drilled holes is only as good as your center-punching ability, so use a fine punch for the first mark and then a bigger one to enlarge the mark enough for drilling.

Access to a drill press is a must. It's extremely difficult to drill holes accurately with a hand drill. Although not absolutely necessary, you should have access to a lathe or milling machine to do the best possible job.

Other tools that will aid you with this project are a nibbling tool, a set of files and some sharp drill bits. If you don't already have one, purchase a file card to clean aluminum and copper shavings out of your files as you work. Clean, sharp files are faster and more accurate to work with. You'll also need an assortment of sandpaper for the final finishing work.

### The Template Approach

It's best to fabricate a single template for marking and drilling the anode plate, anode bypass capacitor, cavity ring, grid plate and front panel. The template shown in Fig. 101 has all of the holes for these parts. If you use the template, you'll only have to make the careful measurements once — after that, it's simple to mark and drill the rest of the parts.

The template approach offers several other advantages. A template makes it much easier to maintain accuracy between the anode plate, cavity ring, grid plate and front panel; these parts will fit perfectly because they were all drilled from the same

master. The template approach also makes it possible to set up a small production line if you decide to build more than one of these amplifiers and combine them for higher power, or if a friend wants to build an amplifier along with you.

See Fig. 101 for complete template dimensions. Start with a piece of 1/16-inch-thick aluminum stock that is larger than you need and degrease it with soap and water. Dry it off and spray it with marking dye. Scribe a 4-inch square on the stock and cut the template to size. A shear will make this job much easier, but it can be cut with hand tools and filed to size.

Carefully measure and scribe all holes. Note that holes A and B are on the circumference of circles. Use a compass to scribe the circles, and then locate the holes. After you have marked and checked all holes, centerpunch and drill them. The holes should be drilled with a 1/16-inch or smaller bit. Recheck all measurements. If you goof, start again. The time you spend making the template as perfect as you can will save you much time and aggravation when you make and assemble the other parts.

When you finish the template, mark the front side for future reference. All plates that will be made from the template are marked and drilled from the front side (as viewed from the front panel).

### Making the Copper Plates

Once you have completed the template,

Fig. 102 — Drilling details for the anode plate. See Fig. 101 for additional information on hole location.

Fig. 103 — Drilling details for the grid plate. See Fig. 101 for additional information on hole location.

Fig. 104 — Drilling details for the anode-bypass-capacitor plate. See Fig. 101 for additional information on hole location.

it will be easy to make the copper plates. The anode plate, grid plate and anode-bypass-capacitor plate are all made from 1/8-inch-thick copper. See Figs. 102, 103 and 104 for the dimensions of these pieces.

Measure and cut the three plates to the proper dimensions. Carefully break (deburr) all sharp edges to avoid small cuts to your fingers and hands.

Clean the plates with alcohol and spray them with marking dye. Clamp the aluminum template to each plate and carefully scribe the correct holes. Remember that all plates do not have the same holes. The anode plate uses holes A, B, C, F and H; the grid plate uses holes

C, D, G and H. The anode-bypass-capacitor plate uses holes B, E and H.

Use a small center punch to punch all holes accurately and lightly. If they then look accurate, enlarge them enough for drilling.

Copper isn't the easiest metal to work with. It's very stringy, and drilling it can be frustrating. You'll need the proper drill bits for best results. Special drills can be purchased, but that's not really necessary. You can use a grinder to carefully remove the sharp points on the outer edge of the cutting surface of each side of a standard drill bit. This will eliminate any tendency for the copper to grab. Practice on an old

bit and be sure to grind it symmetrically. Modified drill bits can still be used on aluminum and other metals.

Always start with a smaller drill and work up to the final hole size. It's safer and more accurate. The larger holes can be cut with a flycutter, or you can drill a series of smaller holes around the inside of a larger hole and file to finish. Either way is fine. Use lots of cutting fluid to lubricate the drill bit, and wear safety glasses and an old shirt. Remember, some cutting fluids are not to be used on aluminum.

Start with a no. 50 (0.070-inch) or smaller bit and drill pilot holes at each of your punched marks. The details for finishing each hole are listed in the drawings. Some holes are countersunk or tapped. Pay attention to the details and take your time.

When you are through drilling, you must deburr each hole. Copper is soft, so it tends to rise up around the hole during drilling and deburring. Use a flat file for the initial cut, and then remove any remaining material with a countersink. File the copper plates flat again because a flush fit on both sides of the aluminum ring is very important.

When all copper work is done, you should be able to stack the plates and see all pertinent holes align correctly. Enough tolerance is included in the dimensions to accommodate minor errors. After the holes are drilled, it can be difficult to tell which side of each plate is which, so mark the front side of each plate with a permanent marker.

### Machining the Ring

The aluminum ring that forms the cavity

Fig. 105 — Details of the cavity ring. See Fig. 101 for additional information on hole location.

wall is cut (sliced) from a length of 3½-inch OD tubing with a 3/8-inch wall thickness. See Fig. 105. The tubing ID is approximately 2¾ inches. The dimensions of the ring are the most critical in this amplifier. Tolerance of the ring thickness is  $\pm 0.005$  inch to maintain full band coverage.

The ring can be hacksawed or band-sawed out of the tubing, but take extreme care to be accurate. Cutting tubing straight isn't easy. Clamp the tubing to prevent rotating on the bandsaw. The final finish cut is best done on a lathe or milling machine, but careful filing will work.

Once the ring is the correct thickness, deburr the sharp edges and spray it with marking dye. Notice that the outside and inside diameters are not concentric. This is normal for large tubing and is not a problem. Lay the ring flat and find the thickest wall section. Scribe a line across the wall at this point, across the center of the ring, and across the wall on the other side. The scribed lines on each side of the ring will be used to align the template. The output connector will be placed at the thick wall section.

Carefully align notch I on the template with the line scribed on the thickest wall section on the ring. Clamp the template onto the ring. Mark each of the 11 holes labeled A on the template. After you mark the holes and remove the template, check alignment with the copper plates just in case. If everything lines up, center punch all eleven holes on one side of the ring only, and drill each hole completely through the

ring. Use lots of cutting fluid. File the ring flat before and after deburring, taking care not to change the wall thickness. Tap each hole to accept no. 4-40 machine screws. Each hole will have to be tapped to a depth of at least 3/8-inch from both sides because long taps don't exist. The inside of the ring doesn't need to be polished.

The hole for mounting the output connector can now be drilled. There are two ways to mount this connector, and either scheme works fine. Read ahead to the section on making the output connector for more information. The first method of mounting the output connector involves tapping the ring with a no. 5/8-24 tap and using a lathe to cut matching threads on the output connector coupling sleeve. Large taps are expensive, but both a tap and die for Type-N connectors come in handy if you do a lot of building.

If you don't have access to a lathe or a large tap, the second method is easier. Make the output connector coupling sleeve from 5/8-inch-OD brass or copper tubing and drill the ring to just clear it. Then drill and tap the grid-plate side of the ring above the output connector to accept a setscrew. Use the setscrew to secure the output connector.

### Output Connector

A standard Type-N chassis-mount female connector (silver plated) is used for the output probe/connector. See Fig. 106. First, remove the flange with a hacksaw and file flush with the connector body.

Next, make the output coupling sleeve that is right for your application (threaded or unthreaded, depending on how you fabricated the ring). The sleeve will be the same length in either case. The output coupling loop is fashioned from a piece of 0.032-inch-thick copper sheet that is 5/32 inch wide. Bend it to the dimensions shown in Fig. 106. We will solder the output connector together later.

### Grid Compartment

The grid compartment measures 2 inches square by 1½ inches high. See Fig. 107. It is made from brass and can be sawed out of square tubing or bent from sheet stock. The cover can be made from any sheet metal.

Two small PC boards (Fig. 108) hold the finger stock that makes contact with the filament pin and cathode ring on the 2C39 tube. These boards are cut from 1/16-inch-thick, double-sided G-10 glass-epoxy stock. The copper pattern is identical for both sides of each piece. Mark and drill or file the holes first and then cut the boards to size. Small boards are difficult to hold while drilling them. Mark each side of each board and score the copper foil with a sharp knife.

The unwanted copper can be removed easily by heating the foil with a soldering iron and lifting it off. Use a flat file to deburr the boards. Do not use a counter-sink because the copper foil must be as close to the holes as possible to facilitate soldering the finger stock in place.

The input connector is a 5-mm SMA type. This is an excellent RF connector, especially for low-power UHF applications. Although an SMA is recommended, any small, screw-on connector will do. If you really feel you have to use a BNC then do so, but it's a lousy connector at frequencies above 200 MHz. Remember to move

**Fig. 106 — Output-probe/connector assembly details.**

Fig. 107 — Input compartment details.

the connector hole to accommodate its larger size.

The input connector must be as close as possible to the first input capacitor. Lead length of the input dc blocking capacitor must be as short as possible. The 3-pF capacitor is series resonant at 1200 MHz only with short (1/16-inch or less) leads.

### Miscellaneous Bits and Pieces

There are still several small, but very important parts to fabricate. The front panel is shown in Fig. 109. It is made from a piece of 1/8-inch-thick aluminum sheet. Some builders may wish to mount the amplifier on a rack panel. Wash and dry your front-panel material and spray it with marking dye. Clamp it to the template and mark the holes. Check the hole alignment with the

Fig. 108 — Cathode and filament PC-board details.

Fig. 109 — Front-panel details.

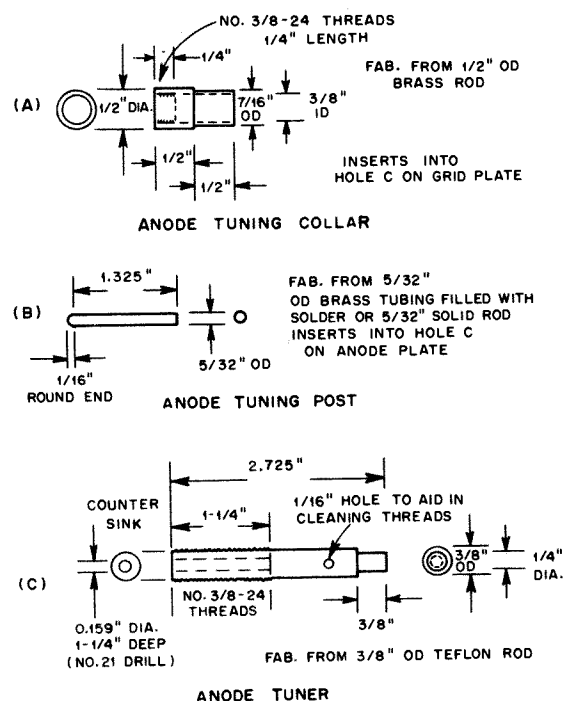

Fig. 110 — Anode-tuning capacitor details.

Fig. 111 — Miscellaneous parts necessary to complete the amplifier.

copper grid and anode plates. If all lines up correctly, center punch and drill the holes. The only front-panel control is for the anode tuning capacitor, which is adjusted by a 1/4-inch shaft protruding through a 3/8-inch panel bushing in hole C.

The anode tuning collar, shown in Fig. 110A, is made from a piece of 1/2-inch-OD brass rod. This rod has a 3/8-inch hole drilled through its center, and it is turned down to 7/16-inch OD for half its length. The inside of the 1/2-inch-OD end is tapped to a depth of 1/4 inch to accept 3/8-24 threads. This collar will be inserted into hole C on the grid plate.

Fig. 110B also shows the anode tuning post. It is simply a length of 5/32-inch-OD brass rod that inserts into hole C on the copper anode plate. This rod will form one plate of the anode tuning capacitor; the cavity wall is the other plate.

The anode tuner (Fig. 110C) is machined from a piece of 3/8-inch-OD Teflon rod. One end of the rod is drilled out with a no. 21 drill. The outer wall of this end is threaded with a no. 3/8-24 tap. This is the end that will thread into the anode tuning collar and slip over the anode tuning post. The other end is turned down to fit inside a 1/4-inch shaft coupler.

Fig. 111 shows the remaining parts. The tuning shaft (A) is made from a piece of 1/4-inch brass rod. A coupler (B) to connect the tuning shaft to the anode tuner can be purchased or made. This also applies to the front-panel spacers (C). The Teflon dielectric for the anode bypass capacitor (D) is made from 0.010-inch-thick Teflon sheet.

Use the template to locate holes B and H. Teflon washers and inserts (E) are used to insulate the mounting hardware for the anode bypass capacitor from the chassis. The inserts are made from 1/4-inch-OD Teflon rod. The washers are made from Teflon sheet. Sharpen a piece of 3/8-inch OD tubing and chuck it up in a drill press. This tool will cut neat, round washers from the sheet.

The box that encloses the anode compartment (Fig. 112) is fabricated from a Bud AU-1083 utility cabinet. Clean the chassis and spray it with marking dye. Secure the template to the side of the enclosure that contacts the anode plate and scribe the holes labeled F. Make sure that these holes line up with the holes on the copper anode plate. If they do, center punch and drill them to size. If air cooling is used, the blower will mount to this box.

#### Soldering the Subassemblies

Once all copper and brass parts are drilled and deburred, they should be cleaned with alcohol and Scotch-Brite®, a nonmetallic pot cleaner, and washed in alcohol again. Set the pieces aside and avoid touching them. Fingerprints will inhibit soldering.

The best way to solder the heavy brass and copper parts is to first build the soldering fixture shown in Fig. 113. This soldering fixture, made from 1/2-inch-thick aluminum plate, will evenly heat the entire assembly to be soldered. Even heating will allow you to do a much better soldering job than you could otherwise.

Fig. 112 — Anode enclosure details.

Fig. 113 — Dimensions of the soldering fixture. See Fig. 101 for more information on hole location.

The aluminum soldering fixture should be preheated on a stove or hot plate until bits of solder placed on its surface just melt. At this point, reduce the heat slightly. Avoid excessive heat. If the copper parts placed on the fixture suddenly turn dark, the heat is too high.

Solder the grid plate assembly first. You will need the copper grid plate, grid finger stock, anode tuning collar and brass input compartment.<sup>1</sup> Look at the drawings again to be sure that you know which parts go where. Insert the grid finger stock into hole H on the grid plate. As viewed from the front-panel side, the curved fingers will protrude out the back side, away from you. Apply liquid or paste flux and set the grid plate in the soldering fixture. The finger

<sup>1</sup>The finger stock for this project is available from Instrument Specialties, P.O. Box A, Delaware Water Gap, PA 18327. Contact them for the name of the closest distributor. The part numbers for this amplifier are: anode bypass capacitor plate, no. 97-70A; grid plate, no. 97-74A; cathode board, no. 97-420A; filament board, no. 97-280A.

stock will fit in hole H in the fixture, allowing the grid plate to rest flush with the surface of the fixture. Next, apply flux to the anode tuning collar and insert it in hole C of the grid plate. Part of the tuning collar will slip into hole C in the soldering fixture. Make sure the collar seats flush with the grid plate. The flux should start to bubble at this point. Carefully apply solder directly to the joints of the installed parts. The solder should melt almost immediately and flow bright and smooth. Next, place the square brass input compartment in place and apply flux. In a few seconds, it can be soldered by running solder around the joints, inside and outside. If you have trouble getting it to flow on both sides, merely tap the brass box aside (1/16 inch) and return it to its original position.

Now comes the hard part — getting the soldered assembly away from the heat without disturbing the alignment. A pair of forceps is recommended, but long pliers will do. Carefully lift the assembly off the soldering fixture and set on a cooling rack. Do this without moving any part. The cooling rack can be any two pieces of metal that will allow clearance for the protruding parts. You can expedite cooling by using an ordinary hair dryer in the “cool” position to gently blow air across the assembly.

While the grid assembly is cooling, assemble the output connector. See Fig. 106. Place the modified Type-N female connector, threaded end down, on the soldering fixture. Apply flux to the top and install the output coupling sleeve. Allow both parts to heat before applying solder. Carefully remove the soldered output connector from the fixture. When it has cooled, solder one end of the loop to the center pin of the N connector and the other to the output coupling sleeve.

Now place the anode plate on the soldering fixture and allow to heat. Apply flux to hole C. Insert the anode tuning post (5/32-inch-OD brass tube) and allow to heat; apply solder. Remove the parts and cool as before.

This completes the work with the soldering fixture. Be sure to let it cool off before handling! Save the fixture for future construction; you never know when you might want it again.

The anode plate and the anode-bypass-capacitor plate must be filed and then sanded flat on their butt surfaces to assure that there are no solder bumps or sharp points to puncture the Teflon dielectric. This must be done after soldering. The Teflon sheet is adequate insulation for many times the anode potential of this amplifier, but only if the surfaces it separates are smooth!

Next, clean the cathode and filament PC boards. Install the finger stock in hole H of the cathode board. Apply flux to both sides of the board. Heat with a hot iron and apply solder around the circumference of hole H, soldering the finger stock on both

Fig. 114 — Assembly details for the filament and cathode boards (A), the anode-bypass capacitor (B) and the input pi network (C).

sides of the board. Use the same technique to install the filament pin.

After all parts have cooled, use a spray can of flux remover to clean them. Slight scrubbing with “Scotch-Brite” pot cleaner will finish them nicely. Congratulations: You have finished the pieces and are now ready to bolt the amplifier together.

#### Silver Plating

Over the years, many people have pushed silver plating as the only way to go. You may wish to silver plate the amplifier components before soldering them together, but it is not necessary. The RF skin conductivity of aluminum and copper is pretty good at 23 cm; these materials are much better than brass. In actual testing with four amplifiers, there was no difference in performance among tin-plated, silver-plated and unplated versions. A nickel-plated

amplifier exhibited 3-dB less gain than the others.

#### Assembly

After fabrication of all parts, assembly is simple. Figs. 114 through 116 show assembly details. Loosely fasten the grid and anode plates to the ring. Mount the input connector and capacitors on the input compartment. Loosely install the cathode and filament boards and their respective spacers. See Fig. 114A.

Now insert a 7289/2C39 tube. This will center up all finger stock. Place the Teflon anode tuner in its collar on the grid plate and screw it most of the way in. Now tighten all of the screws. The 7289/2C39 tube should slide in and out snugly, and the anode tuner should screw in and out smoothly.

The Teflon sheet and anode bypass

capacitor plate can be installed now (Fig. 114B). Assemble the remaining input components, the filament feed-through capacitors and RFCs (Fig. 114C). Screw the output probe into the cavity ring (or push in the probe and tighten the set screw, depending on which method you chose). Install the high-voltage connector and other parts in the anode box. Mount the amplifier on the front panel and install the anode tuner shaft. This completes the assembly.

### Power Supplies

The filament and bias supplies for the cavity amplifier are shown schematically in Fig. 117. The manufacturer's specification for the 7289/2C39 filament is 6.0-V ac at 1 A. The use of a standard 6.3-V ac, 1-A transformer only slightly increases the tube emission without much loss of tube life. The filament should be allowed to warm up before operating the amplifier, so the filament, bias and high-voltage supplies incorporate separate primary switches.

### Biasing

Many biasing schemes have been published for grounded-grid amplifiers. Fig. 117 shows a bias network that satisfies all of the following operating requirements:

- 1) External bias supply referenced to ground.
- 2) Low-power components.
- 3) Variable bias to accommodate tube-to-tube variations.
- 4) TR switchable with relay contact or transistor to ground.
- 5) Bias-supply protection in case of a defective or shorted tube.

U2 provides a variable bias-voltage

source, adjustable by R1. The output of U2 drives the base of Q1, which is used to increase the current-handling capability of the bias supply. Q1 must be mounted on a heat sink. J1 is connected to the station TR switching system so that R1 is grounded on transmit and disconnected on receive. The approximate range of the bias supply is 6 to 20 V. Z1 and Z2 provide protection for R1 in case of a shorted tube. The amplifier can be run without Z1 and Z2 if you keep the anode voltage below 1100 V.

### High-Voltage Power Supply

A safe, reliable high-voltage power supply is described here. Of course, you can use any readily available HV supply; keep in mind, however, that the 7289/2C39 anode potential should never exceed 1400-V dc at full load and that the amplifier will withstand 1900-V dc at low cathode current and cut-off-bias conditions. For maximum power output, assuming adequate drive power is available, anode voltage under full load should be about 1200- to 1400-V dc.

Fig. 118 is a schematic diagram of the high-voltage supply. A power transformer (T2) that delivers 900- to 1050-V ac is ideal. The type of rectifier circuit used will depend on the type of transformer chosen. Each leg of the rectifier is made from two 1000-PIV, 3-A silicon diodes connected in series. Each diode is shunted with a 0.01- $\mu\text{F}$  capacitor to suppress transient voltage spikes, and a 470-k $\Omega$  equalizing resistor.

Filtering is accomplished with a string of four 360- $\mu\text{F}$ , 450-V electrolytic capacitors connected in series. R3-R6 equalize the voltage across each capacitor in the string

and serve as bleeder resistors. Of course, a single oil-filled capacitor may be used here if available. Whatever type of filter you use, the total capacitance should be about 80  $\mu\text{F}$  at a voltage rating of at least 1500-V dc. This value allows adequate "droop" of the anode voltage under high-current loads to protect the amplifier in case of RF overdrive or a defective tube.

### Protective Circuitry

Some type of start-up protection should be incorporated in the primary. Fully discharged filter capacitors look like a dead short at supply turn-on. Initial surge current (until the capacitors charge) may be high enough to destroy the rectifiers. R1 and R2 provide some surge-current limiting, but either of the two primary configurations shown in Fig. 118 should be used. T1, a variable autotransformer (Variac and Powerstat are two common trade names), is ideal. In addition to allowing you to bring the primary up slowly, (and charging the capacitors gradually), it also allows full control of amplifier output power by varying anode voltage.

The second method, a "step-start" system, uses a resistor in the T2 primary to limit the turn-on surge current. When the capacitors have charged, K1 is energized, shorting out R1 and applying full voltage to the T2 primary.

F1 and R7 protect against high-voltage arc-overs or short circuits. If sustained overcurrent is drawn, F1 will open and remove B+ from the RF deck. Use a high-voltage fuse here; standard fuses may arc when blown and not interrupt the B+. R7

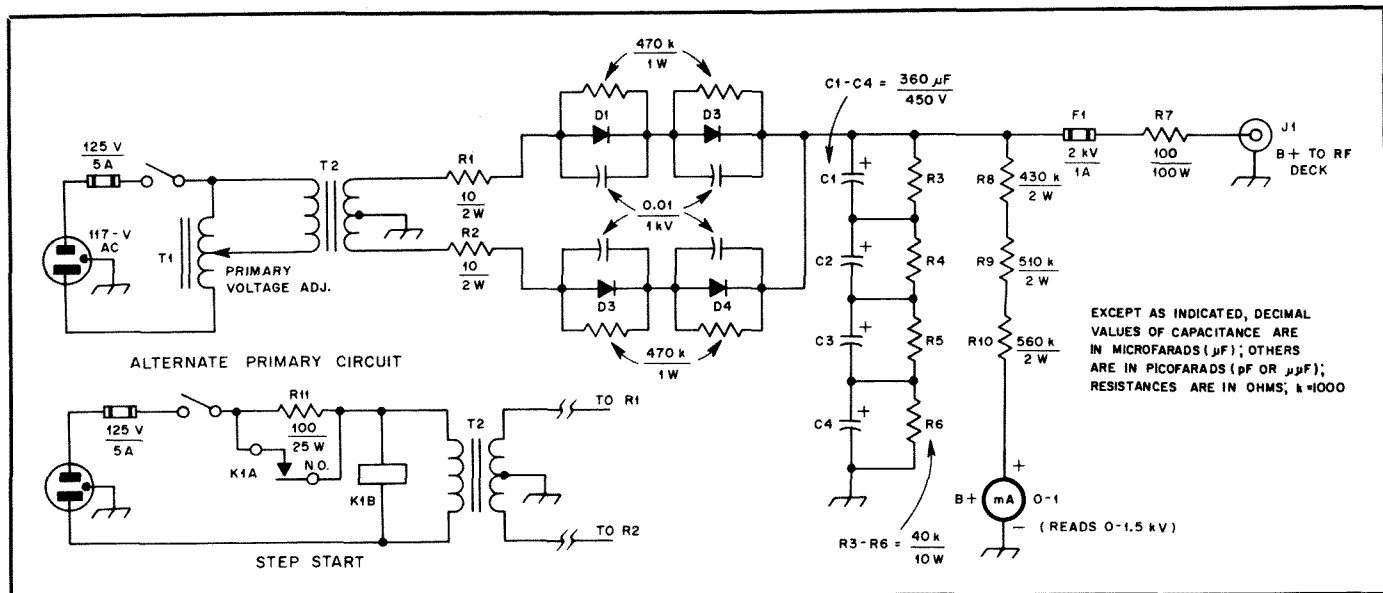

Fig. 118 — Schematic diagram of the amplifier high-voltage supply.

C1-C4 — Electrolytic capacitor, 360  $\mu$ F, 450 V.  
D1-D4 — Silicon rectifier, 1000 PIV, 3 A.  
F1 — High-voltage fuse, 2 kV, 1 A.

J1 — Chassis mount female BNC or  
MHV connector.  
R3-R6 — Wirewound resistor, 40 k $\Omega$ , 11 W.

T1 — Variable autotransformer, 500 VA.  
T2 — High-voltage transformer. Primary,  
117 V; secondary, 900 to 1050 V at 500 mA.

provides current limiting to protect the amplifier and power supply in case of a high-voltage arc.

### Safety

An HV meter should always be used to monitor the status of the power supply. The values for R8-R10 shown in Fig. 118 will give a 1500-V dc full-scale reading on a 0-1 mA meter. RG-58 or -59 coaxial cable should be used for the high-voltage interconnection between the power supply and the RF deck. Ground the shield at both ends for safety and a good dc return.

Safety must be observed when working with all power supplies. These voltages are lethal! Always disconnect ac power and then discharge the filter capacitors before working on the power supply. Never guess or make assumptions about the status of a power supply. Assume it is hot.

### Metering

Cathode-current monitoring is all that's really necessary for observing amplifier dc performance. Cathode current ( $I_K$ ) is the sum of the plate ( $I_P$ ) and grid ( $I_G$ ) currents. Normally, when this amplifier is driven to 300- or 400-mA  $I_K$ , the grid current will be around 40 to 50 mA. The inclusion of a grid-current meter is not really necessary and only makes biasing and TR switching complicated.

### Cooling

Desired output power and the level of drive power available will dictate what type of cooling to use. For intermittent duty (SSB, CW) at output levels less than 50 W, air cooling is satisfactory. Any small blower may be easily mounted to the aluminum box surrounding the tube anode. For high-duty-cycle modes and/or output levels

greater than 50 W, water cooling is highly recommended. Greater than twice the normal air-cooled output power can be obtained from a water-cooled tube, and water cooling is quiet.

### Tube Modification and Water Jacket

The first step is to remove the air radiator from the tube. The air radiator screws on, so it may simply be unscrewed without damage to the tube.

First, place a hose clamp around the tube anode. Secure the radiator fins in a vise and grip the hose clamp with a pair of large pliers. Gently unscrew the tube from the radiator. If the hose clamp slips slightly, tighten it.

Some 7289/2C39 tubes use an air radiator that is attached with set screws. To remove the radiator, simply remove the set screws and pull the radiator off.

The air radiator will be replaced with a water jacket that allows water to be circulated past the tube anode and through a heat exchanger, where it is cooled and circulated past the tube anode again. Two different types of water jackets are described here.

The water jacket shown in Fig. 119 will work with any type of 7289/2C39. It is fabricated from a 1-inch-OD copper tubing cap and two short pieces of 9/32-inch OD brass tubing. The copper tubing cap should be available from a local hardware store or plumbing supply house. Brass tubing is available from many hobby stores and metal supply houses.

Mark and drill the copper cap so that the brass tubing is a snug fit. Thoroughly clean the parts until they shine. Push the tubing into the holes in the end cap and degrease the assembly with alcohol. Use plenty of flux and solder the seam around each sec-

tion of tubing. Allow the jacket assembly to cool.

Meanwhile, thoroughly clean the 7289/2C39 anode to a bright finish. Check the water jacket for fit. In some cases, you'll have to use a 0.005- to 0.010-inch-thick copper shim to fill the gap between the copper cap and the tube anode. This shim helps eliminate pin holes in the solder.

Using plenty of flux, solder the water jacket to the tube anode. Solder it quickly with a hot, high-wattage iron. Allow the tube to cool in the air after soldering to avoid thermal shock and possible breakage. After the tube has cooled, use plenty of alcohol to remove all traces of flux from the tube and water jacket.

The second type of water jacket is shown in Fig. 120. This jacket will work only with 7289/2C39 tubes that have a screw-on air radiator. It is designed to thread onto the tube anode just like the air radiator did. This jacket is machined from a piece of 1 1/4-inch aluminum rod. The water inlet

Fig. 119 — Details of the solder-on water jacket.

Fig. 120 — Details of the screw-on water jacket.

and outlet tubes are made from 9/32-inch-OD, 1/4-inch-ID aluminum tubing that is epoxied in place. A rubber gasket seals the jacket against leaks.

If you have access to a lathe, you should have no trouble duplicating the jacket. You could have one made up at a local machine shop. Complete screw-on water jackets are also available from Angle Linear.<sup>2</sup>

After you unscrew the air radiator from the 7289/2C39, check for and remove any burrs from the tube anode. The anode surface must be flat if the rubber gasket is to be effective. Screw the water jacket onto the tube. Tighten by hand only. Do not use any tools, or you could damage the tube or jacket! Do not use the water inlet and outlet tubes for leverage — they have thin walls and break easily.

### Water System

Fig. 121 depicts the complete water-cooling system. Recommended pumps and accessories that have proven reliable and effective are listed in the caption.

Any small pump, such as a fountain pump, that can deliver 160 to 200 gallons

per hour can be used here. Most inexpensive pumps are not self-priming, which means that they won't pump water if they have air in the rotor. Although water can be forced through the pump for the initial prime, my system uses gravity priming. The water reservoir is a 2-foot length of 3-inch-OD plastic pipe that is available from hardware or plumbing stores. It is usually sold for use in residential sewer systems. The outlet is at the bottom and the inlet about halfway up the column. The inlet is located here to eliminate aeration that ionizes the water and reduces its effectiveness. The outlet feeds the pump directly. The pump and the reservoir outlet port should be mounted in the same plane. The pump should be oriented so that air bubbles will rise into the impeller output port and can be blown out once the pump starts running.

### Flow Indicator and Heat Exchanger

Water cooling is best described as "super quiet." There is no noisy fan to hear to reassure you that the tube is receiving adequate cooling. If water flow is reduced or cut off during amplifier operation, tube damage is virtually assured.

Flow interlocks and switches to shut down the amplifier if water flow is reduced are hard to find and expensive. Flow in-

dicators, however, are inexpensive and reliable. A flow indicator has a spoked rotor that turns as water passes through the unit. If the wheel is turning, there is water flow; if not, you have a problem. Changes in flow rate can be observed by watching for speed changes in the rotor. A small lamp illuminates the flow indicator, making it easy to see rotation. The flow indicator should be mounted where it can be seen from the operating position and monitored during operation.

Heat exchangers, or radiators, remove the heat from water as it passes through. For this application, a small automobile transmission-oil cooler works great. Most auto-parts stores and speed shops have a good selection. Some come with mounting brackets. Look for a cooler with the input and output ports on the top so air bubbles will rise to the top and move on without becoming trapped. Trapped air degrades cooler performance.

If you use the amplifier for high-duty-cycle modes such as ATV or FM, or for long, slow-speed CW transmissions (EME, for example), you should use a small axial whisper fan to increase the effectiveness of the heat exchanger. A fan isn't necessary during normal operation, or even for sustained operation at moderate power levels, but is highly recommended if you plan prolonged operation at maximum power. Locate the fan so the warm exhaust air won't heat up other equipment.

### Hoses and Fittings

Most hardware stores carry a complete line of brass fittings and adapters that can be used for this project. Brass, however, will eventually corrode and pollute the water supply. Plastic fittings are cheaper and don't corrode, but they are harder to find. Recreational vehicle suppliers are my main source for these parts. They are used extensively in drinking water systems for mobile homes and travel trailers. Procure the fittings when you have the rest of the parts in hand, as there are many variables to consider.

You can use any relatively soft, thin-wall vinyl tubing for all water lines. The main runs are made from 3/8-inch-ID hose, while 1/4-inch-ID stock is used to connect to the 7289/2C39 water jacket. The 1/4-inch-ID tubing fits snugly over the 9/32-inch-OD inlet and outlet tubes on the water jacket, so no clamps are required. All other hose connections should be secured with stainless-steel clamps to prevent leaks. Any leaks mean air in the system and deterioration of cooling performance.

### Safety

The anode of the tube, and hence the water jacket and water, are in direct contact with the high-voltage supply, so some safety precautions must be observed. Approximately 12 to 18 inches of tubing should run between the 7289/2C39 jacket and any other component in the cooling

<sup>2</sup>25309 Andree Ave., Lomita, CA 90717.

It is best to ground the water supply at the pump. This can be accomplished by replacing a short section of the tubing that runs to the flow indicator with a piece of brass or copper tubing. Solder a wire to this metal tubing and connect the other end of the wire to your station ground. Use at least 24 inches of vinyl tubing between the anode

On the warm-water side of the 7289/2C39, run 12 inches of vinyl tubing to a small metal fitting or short section of metal tubing, and then another 12 inches of vinyl tubing to a grounded point (this can be at the heat exchanger). You can measure the water leakage current to ground by placing a microammeter between the metal fitting that connects the two vinyl hoses and ground. Leakage current should be less than 10  $\mu\text{A}$  with clean

Water was chosen because it's inexpensive, nontoxic, nonflammable, and easy to clean up if you have a leak. Better liquid coolants are available, but they are toxic. Don't use them!

Fig. 122 is a graph of several transmit/receive cycles on a water-cooled, 500-W output, 23-cm power amplifier. For this test, two of the amplifiers described here were coupled with a hybrid combiner. This particular cooling system used one gallon of water. Experiments indicate that, during extended operation, the water temperature rises only 30 to 35°F above ambient room temperature. Typically, the tube anode and water average 10 to 15°F above ambient during casual operating.

Flow rates in this system are typically  $\frac{1}{3}$  gallon per minute per tube, which is more than adequate. At this rate, more than 300 W of dissipation from a single inefficient 7289/2C39 were required to boil the water in the water jacket. The water should not be allowed to boil because this will heat the rubber gasket.

It is not really necessary to buy a new 7289/2C39. Used tubes can be found surplus for a few dollars and, in many cases, will perform as well as a new tube. Most used tubes have been sitting around for several years, so it's a good idea to run them through the dishwasher to clean them up and then run the filaments for about 24 hours. This will restore operation in many cases.

Contrary to popular opinion, glass tubes will work. Physically, they are not as rugged as the ceramic version, but the glass-to-metal seal seems to provide better shelf life than the ceramic seal. The glass tubes make great driver tubes and will work fine for power levels up to 100-W output. Pulse tubes (7815, 7211) are not recommended because of their poor thermal stability at high power levels. Also, they generally are

## Microwave Radiation Safety

Intense RF radiation concentrated on body tissues can produce heat damage; the extent and penetration will depend on the radio frequency in use and on exposure duration. You should be aware of the approximate intensity of RF radiation of transmitting equipment and antennas that you come in contact with.

RF intensity is commonly expressed in milliwatts per square centimeter (mW/cm<sup>2</sup>), which is the power flowing away from a source through a unit sampling or interception area at some specified distance. Although the United States as yet has no federal RF protection standard, a useful interim guide is the 1982 standard of the American National Standards Institute (ANSI '82). The most stringent level in this standard is 1 mW/cm<sup>2</sup> for frequencies between 30 and 300 MHz. Above 300 MHz, the protection level rises until it reaches 5 mW/cm<sup>2</sup> at 1500 MHz. Beyond 1500 MHz, the recommended level remains at 5 mW/cm<sup>2</sup>. These levels represent the average power density allowed over any six-minute period and are for the sum of all polarizations from a given source.

At 1296 MHz, where one wavelength ( $\lambda$ ) equals 23 cm, a thick resonant dipole feeding a calibrated power meter with matched coaxial cable (itself free of pickup) may be used to obtain an indication of power density. A reasonably lossless resonant dipole has an effective aperture of  $\lambda^2/8$ ; at 23 cm this is 66 cm<sup>2</sup>. The power meter reading in milliwatts, divided by 66, is the indicated power density. For this to be a reliable indication, the dipole must be positioned far enough from the RF source to be in its far field. For a small source, the distance should be at least  $\lambda/2$ , and here that would be about 12 cm (4.5 inches). The dipole should be oriented for alignment with the dominant polarization. Note that the power meter must be capable of readings well below 1 mW.

This arrangement would be useful for checking leaks along the coaxial route that the high power (here 250 W) takes to a load, be it dummy load or antenna. Cable connectors may not be tightly secured, or they may be faulty. For equipment operating in the SHF region, waveguide flanges may not be clamped properly.

Direct measurement of electric field strength near an antenna (with a calibrated instrument, preferably one with the indicating meter shielded and possibly positioned at the center of the sampling dipole) is another way to check for adequate protection. A field strength of 60 V per meter (V/m) corresponds to 1 mW/cm<sup>2</sup>; 134 V/m corresponds to 5 mW/cm<sup>2</sup>. At a distance 60 cm (2 feet) from an isolated dipole fed with 26 watts, the field strength would be about 60 V/m. This is a far-field field strength for all frequencies where the half wavelength is less than 60 cm, or for frequencies above 250 MHz. For full 250 watts applied to the dipole, the 60 V/m level occurs at a distance of 1.8 meters (6 feet) and at this distance this holds for all frequencies above 80 MHz.

With SSB or CW keying, the fields during Amateur Radio operation are highly intermittent, and usually include considerable pauses or intervals for listening. These factors reduce the average power density over the six-minute averaging period.

Further information on RF safety and protection estimates can be found in Chapter 7 of *The Satellite Experimenter's Handbook*, published by ARRL. The following rules of good practice for RF protection are recommended:

- Never operate an RF amplifier with equipment shielding removed.
- Never handle antennas with RF power applied.
- Never guess that RF levels are safe. Take the time to consult a reliable reference for an estimate, or measure levels carefully. Allow a cushion of about 6 dB (factor of 4 in power density). If possible, borrow an RF radiation monitor (after learning how to use it), or consult with a ham who is well informed on RF protection.
- Never look into an open end of a power waveguide; never point a powered directive antenna (a beam or a paraboloid, for example) toward people. Keep all VHF and UHF transmitting antennas up as high as possible, distant from human activity.
- Use good-quality, well-constructed, coaxial cable and connectors to avoid RF leaks.
- Think RF and electrical safety first; test later!
- Watch QST for news on RF measurement techniques and progression, protection standards and proposed federal and state RF regulations. — David Davidson, W1GKM

30 to 40 MHz lower in resonant frequency in this amplifier compared to the 7289/2C39. Some 7289 tubes can be as much as 30 MHz lower in frequency. Minor length adjustment of the anode-tuning post may be required to accommodate amplifier and tube differences.

## Tube Insertion

Extreme care must be exercised when inserting the 7289/2C39 tube. Never force the tube in place as damage (bending) of the cathode finger stock may result. Observe the layout of the finger stock to get an idea of how the tube inserts. Carefully position the tube so it is straight as you gently push. It should slide in snugly without any solid resistance.

## Testing

After you have completed all of the parts for the amplifier, it's time to test everything before hooking it all together. Test the water-cooling system by turning it on and

watching for steady water flow as indicated on the flow meter. The tube and water jacket can be removed from the cavity amplifier for this test.

Check all of the power-supply voltages first without connecting them to the RF deck. Then, without the tube in place, hook the bias and filament supplies to the cavity and check the voltages again at the tube finger-stock connections. Connect the high-voltage supply to the RF deck and bring the voltage up slowly with a variable autotransformer. Monitor the high-voltage on the anode bypass capacitor plate, and look and listen for any possible arcing between the anode-bypass-capacitor plate and ground. Use extreme care when measuring and testing the high-voltage supply. If everything looks okay with the power supplies, shut them off and disconnect them.

You can make a safe, low-power test of the cavity resonance without applying any voltage. With the tube in place, insert a

2-inch-long coupling loop on the end of a piece of coaxial cable between the spring fingers of the anode down into the cavity. Connect the amplifier output probe/connector to a device capable of detecting low-level RF at 23 cm (for example, a spectrum analyzer or microwattmeter). Feed a signal from an L-band signal generator into cable attached to the wire coupling loop that you inserted into the cavity. Set the signal generator for various frequencies in the 23-cm band and tune the amplifier anode tuner. There will be a sharp peak in output at cavity resonance.

This testing method can be used to determine cavity tuning range, anode-bypass-capacitor effectiveness and resonance of various tube types for use in this amplifier. Any cavity amplifier can be tested completely without ever applying high voltage. The better your test equipment, the easier the amplifier is to test. If all dimensions were followed strictly, the amplifier will tune as designed.

## Amplifier Hookup

Installation and operation of this amplifier is relatively straightforward, but as with any amplifier, several precautions must be followed. If these are adhered to, it will provide years of reliable service.

The amplifier is designed to be operated in a 50-ohm system and should never be turned on without a good 50-ohm load connected to the output connector. Never operate it into an antenna that has not been tuned to 50 ohms!

Drive power to the amplifier should never exceed 15 W. Never apply drive power in excess of 1 W unless all operating voltages are present and the tube is biased on. Otherwise, the tube grid-dissipation rating will be exceeded and you will probably ruin it.

As in all TR-switched systems, some type of interlock or sequencing of transmit and receive functions should be incorporated. In most systems, the sequence for going into transmit is something like this: First, switch the antenna changeover relay from the receiver to the power amplifier. Next, bias the power amplifier on. Last, key the exciter and apply drive to the amplifier. To go to receive, unkey the exciter, remove operating bias from the amplifier and switch the antenna relay back to the receiver. A TR sequencer is described in Chapter 31.

If the antenna relays are switched while the power amplifier is operating and putting out power, damage to the relay contacts and/or the amplifier is likely. If there is a momentary removal of the antenna while the power amplifier is biased on, it may oscillate. This can damage the TR relay, the tube, or even the receive preamplifier.

## Tune Up and Operation

This is it — the big moment when you will see your project come to life! Connect

Fig. 123 — Performance of the cavity amplifier under different drive and plate-current conditions.

an accurate UHF power meter and a 50-ohm antenna or load to the amplifier output connector. A Bird Model 43 wattmeter with a 100- or 250-W, 400- to 1000-MHz slug will give reasonable accuracy, depending on the purity of the drive signal. Apply filament power and tube cooling, and allow 3 to 5 minutes for the filaments to warm up. Turn on bias supply (the amplifier will draw maximum current if the anode voltage is applied without bias). Apply 300 to 400 V to the anode. There should be no current flowing in the tube as indicated on the cathode-current

meter. Ground J1 on the bias supply to apply transmit bias and observe cathode current. As R1, the bias control, is turned clockwise, quiescent idling current should increase. Set for about 25 mA.

Apply 1 W of RF drive power. Turn the anode tuner while observing the RF output power meter and tune for maximum output. The output should go through a pronounced peak at cavity resonance. Adjust C2 and C3 on the input tuning network for maximum amplifier output. If possible, use a directional wattmeter between the driver and the amplifier input to check that best input SWR and maximum amplifier output occur at roughly the same setting.

Depending on the amount of drive power available, you may want to tune the amplifier for maximum power output or maximum gain. Fig. 123 shows what you can expect from different drive levels.

Once the amplifier is tuned for best input SWR and maximum output with 1 W of drive, anode voltage and drive power can be increased. Increase both in steps; be sure to keep the anode tuner peaked for maximum output power. When you get to the 100-W output level, very carefully readjust the input circuit for maximum output. The input capacitor closest to the cathode is critical and should need to be rotated less than 90 degrees maximum. Maximum output power will be roughly coincident with best input SWR.

Increase the drive power and keep the anode tuner peaked for maximum output. Increase the drive until you reach the desired output level, but do not exceed 400-mA  $I_K$ ! At 1300-V dc and 350-mA  $I_K$ ,

output power with a good tube should be about 230 to 250 watts. At lower anode voltages,  $I_K$  will be higher for the same output power. Higher anode voltages result in higher gain, lower drive levels, lower grid current and lower plate current for a given output power.

The anode tuner's tuning rate is approximately 5 MHz per turn. Clockwise rotation of the tuner lowers the resonant frequency of the cavity. This control will require readjustment as you make large frequency excursions within the 23-cm band (for example, if you go from 1296 weak-signal work to the 1269-MHz satellite segment). You should also check the input SWR if you move more than 15 MHz. Generally, amplifier tuning does not change much after initial setup. You should be able to turn it on and use it without retuning as it heats up. Slight adjustments may be necessary, however, depending on cooling, inherent thermal differences from tube to tube and duty cycle of the operating mode. Always keep the anode tuner peaked for maximum output, and check it from time to time, especially while you are first learning how the amplifier operates.

The output loading control is the output connector and probe assembly. Loading is changed by minor rotational adjustment of the Type-N connector. First loosen the jam-nut (or set screw) slightly. While observing output power and keeping the anode tuner peaked, rotate the loading control  $\pm 30$  degrees maximum for greatest output power. This should be done only once and should not need repeating unless another tube is installed. Even then it may not be required.

## Loop Yagis for 23 CM

Described here and shown in Figs. 124 through 128 are loop Yagis for the 23-cm band. Several versions are described, so the builder can choose the boom length and frequency coverage desired for the task at hand. Mike Walters, G3JVL, brought the original loop Yagi design to the amateur community in the 1970s. Since then, many versions have been developed with different loop and boom dimensions. Chip Angle, N6CA, developed the antennas shown here.

Three sets of dimensions are given. Good

performance can be expected if you follow the dimensions carefully. Recheck all dimensions before you cut or drill anything! The 1296-MHz version is intended for weak-signal operation at 1296 MHz, while the 1270-MHz version is optimized for FM and Mode L satellite work. The 1283-MHz antenna provides acceptable performance from 1280 to 1300 MHz.

These antennas have been built on 6- and 12-foot booms. Results of gain tests at VHF conferences and by individuals around the country peg the gain of the

6-footer at about 18 dBi, while the 12-foot version provides about 20.5 dBi. Swept measurements indicate that gain is about 2 dB down from maximum gain at  $\pm 30$  MHz from the design frequency. SWR, however, deteriorates within a few megahertz on the low side of the design center frequency.

### The Boom

The dimensions given here apply only to a  $\frac{3}{4}$ -inch-OD boom. If you change the boom size, the dimensions must be scaled

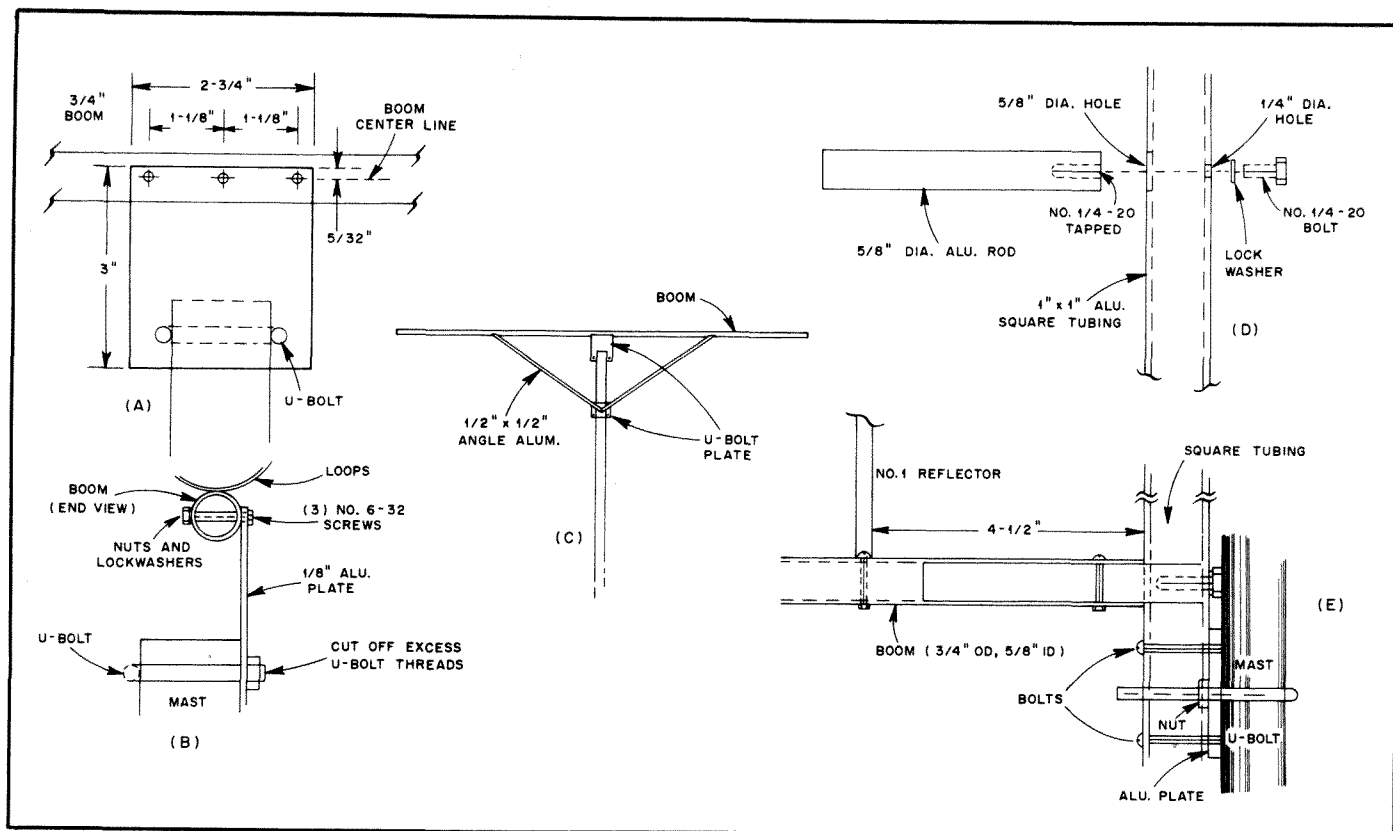

Fig. 124 — Boom-to-mast plate details are given at A. B shows how the Yagi is mounted to the mast. A boom support for long antennas is shown in C. The arrangement shown in D and E may be used to rear mount antennas up to 6 or 7 feet long.

accordingly. Many hardware stores carry aluminum tubing in 6- and 8-foot lengths, and that tubing is suitable for a short Yagi. If you plan a 12-foot antenna, you should find a piece of more rugged material, such as 6061-T6 grade aluminum. Do not use anodized tubing. The 12-foot antenna must be supported to minimize boom sag. The 6-foot version can be rear mounted. For rear mounting, allow 4.5 inches of boom behind the last reflector to eliminate SWR effects from the support.

The antenna is mounted to the mast with a gusset plate. This plate mounts at the boom center. See Fig. 124. Drill the plate-mounting holes perpendicular to the element-mounting holes, assuming the antenna polarization is to be horizontal.

Elements will be mounted to the boom with no. 4-40 machine screws, so a series of no. 33 (0.113-inch) holes must be drilled along the center of the boom to accommodate this hardware. Fig. 125 shows the element spacings for different parts of the band. Tolerances should be followed as closely as possible.

#### Parasitic Elements

The reflectors and directors are cut from 0.0325-inch-thick aluminum sheet and are 1/4 inch wide. Fig. 126 indicates the lengths for the various elements. These lengths apply only to elements cut from the specified material. For best results, the element strips should be cut with a shear. If you

Fig. 125 — Boom drilling dimensions. Pick the version you want and follow these dimensions carefully. Spacing is the same for all directors after D6. Use as many as needed to fill up your boom.

leave the edges sharp, birds won't sit on the elements!

Drill the mounting holes as shown in Fig. 126. Measure carefully! After the holes are drilled, you must form each strap into a circle. This is easily done by wrapping the element around a round form (a small juice can works great).

Mount the loops to the boom with no. 4-40 × 1-inch machine screws, lock washers and nuts. See Fig. 127. It's best to use stainless-steel or plated-brass hardware for everything. Although the initial cost is

higher than for ordinary plated-steel hardware, stainless or brass hardware won't rust and need replacement after a few years. Unless the antenna is painted, it will definitely deteriorate.

#### Driven Element

The driven element is cut from 0.0325-inch copper sheet and is 1/4 inch wide. Drill three holes in the strap, as detailed in Fig. 126. Trim the ends as shown and form the strap into a loop similar to the other elements. This antenna is like a

Fig. 126 — Parasitic elements are made from aluminum sheet. The driven element is made from copper sheet. The dimensions given are for 1/4 inch wide by 0.0325-inch-thick elements only. Lengths specified are hole-to-hole distances; the holes are located 0.125 inch in from each element end.

Fig. 127 — Element-to-boom mounting details.

Fig. 128 — Driven element details. See Fig. 126 and the text for more information.

quad; if the loop is fed at the top or bottom, it will be horizontally polarized.

Driven-element mounting details are shown in Fig. 128. A mounting fixture is made from a 1/4 20 × 1 1/4 inch brass bolt. File the bolt head to a thickness of 0.125 inch. Bore a 0.144-inch (no. 27 drill) hole lengthwise through the center of the bolt. A piece of 0.141-inch semi-rigid Hardline (UT-141 or equiv.) will mount through this hole and connect to the driven loop. The point at which the UT-141 passes through copper loop and brass mounting fixture should be left unsoldered at this time to allow for matching adjustments when the antenna is completed, although the range of adjustment is not that great.

The UT-141 can be any convenient length. Attach the connector of your choice (preferably Type N). Use a short piece of low-loss RG-8 size cable (or better yet, 1/2-inch Hardline) for the run down the boom and mast to the main feed line. For best results, your main feed line should be the lowest-loss 50-ohm cable obtainable. Good 7/8-inch Hardline measures at 1.5 dB per 100 feet and virtually eliminates the need for remote mounting of the transmit amplifier.

#### Tuning the Driven Element

If you built the antenna carefully to the dimensions given, the SWR should be fine. Just to be sure, check the SWR if you have access to test equipment. You must be sure that your signal source is clean, however; wattmeters are often fooled by dirty signals and can give erroneous readings. If you have a problem, recheck all dimensions. If they look okay, a minor improvement may be realized by changing the shape of the driven element. Slight bending of reflector 2 may also help optimize SWR. When you have obtained the desired match, solder the point where the UT-141 jacket passes through the loop and brass bolt.

Quite a few people believe that practices common on lower frequencies can be used on 1296 MHz. That's the biggest reason that they don't work all the DX that there is to be worked!

First, when you have a design that's proven, copy it exactly — don't change it! This is especially true for antennas. Use the best feed line you can get. Why build an antenna if you are going to use lossy cable?

Here are some realistic measurements of common coaxial cables at 1296 MHz (loss per 100 feet): RG-8, 213, 214 — 11 dB; 1/2 inch foam/copper Hardline — 4 dB; 7/8 inch foam/copper Hardline — 1.5 dB.

Mount the antenna(s) to keep feed line loss to an absolute minimum. Antenna height is less important than keeping the line losses low! Do not allow the mast to pass through the elements, like on antennas for lower frequencies! Cut all U-bolts to the minimum length needed — a quarter wavelength at 1296 MHz is a little over 2 inches! Avoid any unnecessary metal around the antenna.

# 10-GHz Gunnplexer Communications

Communications on the amateur 10-GHz band have been simplified greatly with the advent of the Microwave Associates Gunnplexer™ transceivers. It is interesting to note that a similar communications system as little as 10 years ago would have required, literally, a rack full of equipment. The Gunnplexer transceiver shown in Fig. 129 will fit conveniently in your hand and is operated from a single 12-V power supply, either ac line operated or batteries! This makes the Gunnplexer ideal for fixed or portable operation.

The Gunnplexer is most often used in wide-band FM systems and is ideal for audio, full-color video and data transfer. With suitable peripheral equipment, systems for full-duplex audio, color video and up to several megabit data transfer are possible. Such high data rates should allow

direct computer-to-computer memory transfer that would not be practical (or legal) on other lower-frequency amateur bands.

## The Gunnplexer

The heart of the Gunnplexer is a Gunn diode oscillator, named after its inventor, John Gunn of IBM. A more detailed discussion of the Gunn diode is presented in Chapter 4. Refer to the cutaway drawing of the Gunnplexer, Fig. 130, for this discussion.

The Gunn diode is mounted with a varactor diode in a resonant cavity. When a regulated voltage is applied to the Gunn diode it oscillates; the frequency of oscillation is determined by the capacitance of the varactor diode and two mechanical tuning screws. The mechanical tuning screws can

be likened to coarse tuning controls and are factory set for the appropriate tuning range. The voltage applied to the varactor diode (1 to 20 V dc) tunes the frequency electronically a minimum of 60 MHz. Power is coupled out of the cavity through a small iris that has been designed as somewhat of a compromise between maximum power output and isolation from changes in diode impedance and load.

The Gunn oscillator is also used to provide the local-oscillator signal for the detector diode. A ferrite circulator couples an appropriate amount of energy into the low-noise Schottky mixer diode and isolates the transmitter and receiver. Because the Gunn oscillator functions as both the transmitter and the receiver local oscillator, the IF at each end must be at the same frequency. Furthermore, the frequencies of the Gunn-

Fig. 129 — View of the Microwave Associates Gunnplexer. A protective resistor and diode are connected from the detector output to ground. A 50- $\mu$ F electrolytic capacitor is connected from the Gunn diode terminal to ground. The Gunnplexer is designed to mate a UG-39/U waveguide flange when the horn antenna is removed.

Fig. 130 — Drawing of the Gunnplexer assembly. The Gunn oscillator assembly consists of a resonant cavity in which is mounted the Gunn diode and varactor diode. The cylinders contain the quarter-wave choke sections, which connect to the diodes. The Gunn oscillator assembly bolts to the mixer assembly, which contains the detector diode and ferrite circulator. A horn antenna bolts to the front of the mixer assembly. (Reproduced with permission from *Ham Radio Magazine*, January 1979.)

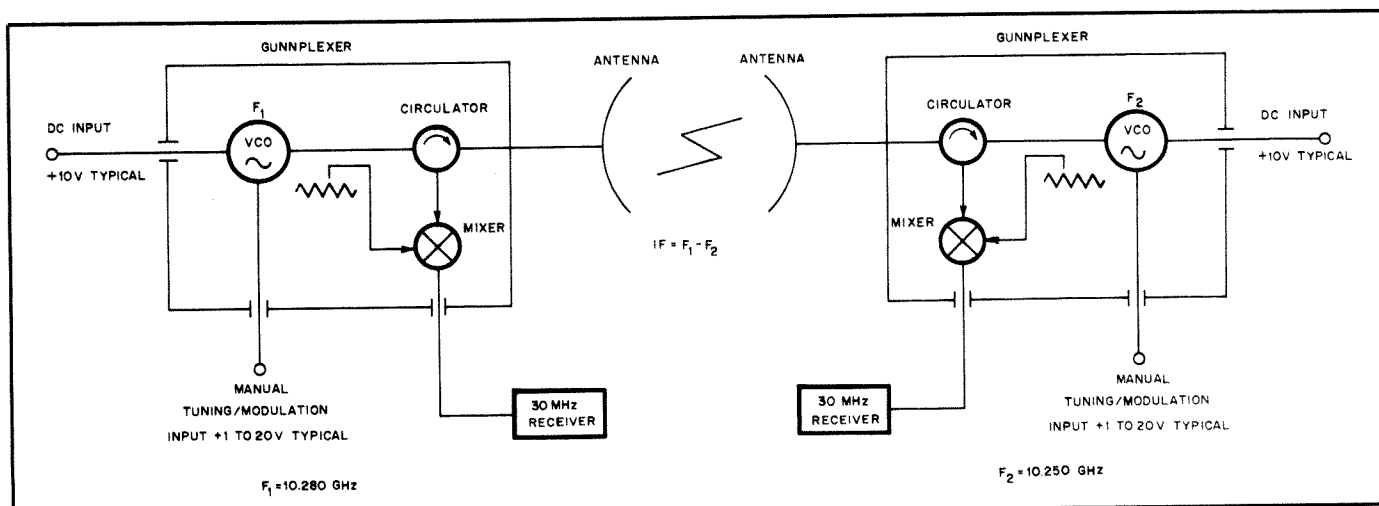

Fig. 131 — This drawing depicts a Gunnplexer communications system running full duplex. The VCOs are offset by the desired IF, which in this case is 30 MHz.

Fig. 132 — Here is a complete bare-minimum communications system using the Gunnplexer transceiver. An inexpensive automobile FM converter or receiver is used for the receiver IF. A 7810 voltage regulator is used for the Gunn-diode supply, and a simple 741 op amp serves as the microphone stage. The frequency of operation is set by the potentiometer that biases the varactor diode. A 10-turn potentiometer provides a comfortable tuning rate.

plexers must be separated by the IF. This is illustrated in Fig. 131. Intermediate frequencies of 30 MHz are more or less standard for audio work in the U.S. Both 45 and 70 MHz are used for video and high-speed data work.

As can be seen from Fig. 131, the Gunnplexer communications system is full duplex. In other words, both parties can talk and listen at the same time, without throwing switches. This is something that may take a while to get used to as most amateurs are programmed for VOX or PTT operation. In short, it is the ultimate break-in system!

One detail of the Gunnplexer that does require some specific attention is frequency control. The Gunnplexer has a frequency-stability specification of  $-350\text{ kHz}$  frequency change per degree Celsius increase. This does not pose much of a problem with wide-bandwidth applications such as video or data transfer. However, for relatively narrowband audio work (200 kHz and less) some form of AFC, a phase-lock or other frequency-control scheme is required. In most cases simple AFC circuitry is suffi-

cient and quite easy to implement. The electrical characteristics of the Gunnplexer are given in Table 12.

#### Bare Minimum Audio Communications System

The simplest of communications systems using the Gunnplexer transceivers can be formed with two 88- to 108-MHz FM receivers, two Gunnplexers, two microphones and associated amplifiers, and two sources of 12 V dc. A diagram of such a system is shown in Fig. 132. Some of the low-cost FM converters and receivers for automotive use make good IF strips for this communications system. The AFC signal developed in the converter or receiver can be routed to the Gunnplexer varactor diode to lock the two units together. The microphone amplifier can be a single 741 operational amplifier as shown in the diagram.

There are two shortcomings with this

system. The first involves the use of the FM broadcast band as the IF. If mountaintop DXing is planned, it is likely that strong FM broadcast stations will be received no matter how short the lead between the detector and the FM converter or receiver is made. It will be necessary to select that part of the band where there are no strong signals present.

The second item involves AFC. Since it is possible to tune the Gunnplexers over a 60-MHz range with the varactor diode tuning, it is possible to tune them on either side of each other. This means that the single-polarity AFC system in the receiver or converter will work for only one combination. If the units are operated so that the AFC polarity is incorrect, the AFC will push the received signal out of the receiver passband. If this happens, simply tune the two Gunnplexers to produce the other IF signal. AFC lock should then be obtained.

# A High-Performance Audio Communications System

The high-performance Gunnplexer audio system described here was developed by Advanced Receiver Research, and is sold as an amateur/commercial product.<sup>1</sup> The information is included here for those who wish to construct their own system.

This Gunnplexer support system has been specifically designed for use with the Microwave Associates Gunnplexers. The board contains a complete 30-MHz FM receiver, diode-switched IF filters, dual-polarity AFC system, Gunn-diode regulator and modulators for phone and CW. The system is suitable for fixed, portable or mobile operation. Power-supply requirements are a nominal 13 volts at 250 mA (this includes the current drawn by the Gunnplexer assembly). The circuit is specified for operation over the temperature range  $-25$  to  $+65^{\circ}\text{C}$ .

## Theory of Operation

The circuit diagram is shown in Fig. 135, and an interconnection wiring guide in Fig. 134. Signal energy arriving at the IF input (pins 24 and 25) is routed to Q1, a low-noise RF amplifier. A band-pass filter, with a 3-dB bandwidth of 2 MHz, is located between the RF amplifier and mixer, Q2. LO injection for the mixer is provided by a crystal-controlled 40.7-MHz oscillator stage. Output from the mixer, at 10.7 MHz, is applied to either of two diode-switched ceramic filters. Supply voltage applied to pin 23 selects FL1 (supplied) and supply voltage applied to pin 22 selects FL2 (optional). Output from the filter is fed to IF amplifier stage Q3. Amplified 10.7-MHz energy is routed to the FM subsystem chip, U1, a CA3189E. Detected audio passes through an AF gain control (pins 16, 17 and 18) to U2, the audio amplifier. This stage has sufficient power to drive headphones and/or a speaker.

Squelch control is available by U5A. U5B inverts the amplified AFC signal so that either polarity AFC may be selected by S3. Overall AFC gain is controlled by  $R_c$ . U5C sums the AFC information along with the manual tuning voltage. This composite signal is applied to the varactor terminal of the Gunnplexer. U5D functions as a meter driver. Its input can be switched for center-tuning (discriminator zero) and manual-tuning voltage. Input to the driver is selected by S1.

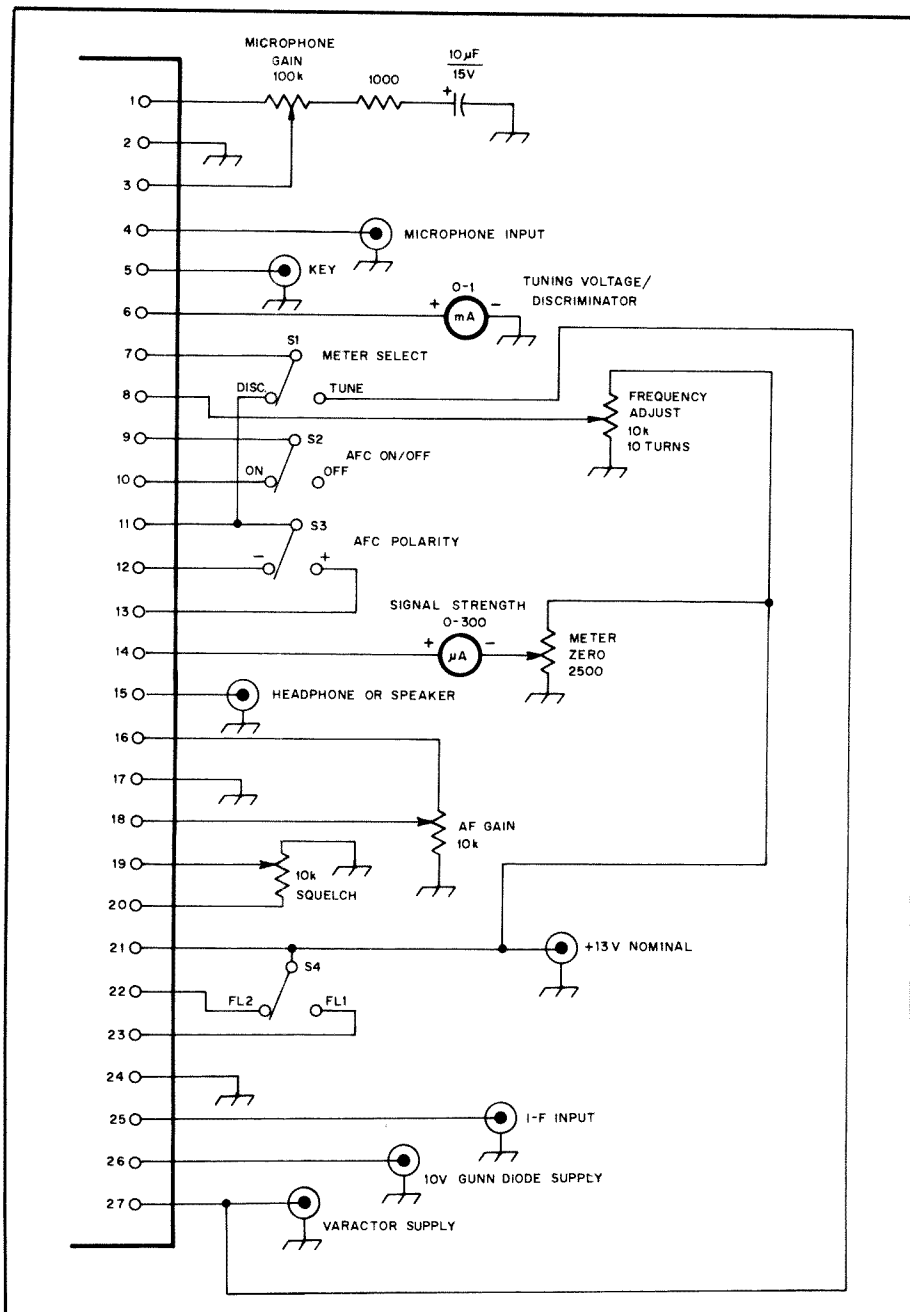

Fig. 134 — Interconnection diagram for the high-performance audio Gunnplexer communications system.

U3 is a microphone amplifier boosting the output from a microphone to a level suitable for modulating the Gunnplexer. U4 generates an approximate 500-Hz tone for MCW operation. Voice and MCW information is applied to the varactor of the Gunnplexer along with the AFC/tuning voltage. U6 is a three-terminal positive

voltage regulator that provides an accurate 10-volt supply for the Gunn diode. A 1N4001 diode is included to protect against inadvertent application of reverse-polarity voltage.

It is advisable to mount the board in a well-shielded enclosure since the receiver is quite sensitive. The Gunnplexer unit can be

RFC4 — 11 turns no. 28 enam. on an FT23-43 core.

Y1 — 40.7 MHz, third overtone.

mounted atop a tower and connected to the board through three lengths of coaxial cable. Although the Gunn diode and varactor line carry only dc and low-level audio signals, shielded cable is a must as even small-voltage pickups can produce relatively large modulating voltages, which are undesirable. In cases of severe pickup, small RF chokes may be required directly at the Gunn diode and varactor connections

of the Gunnplexer. Lengths of cable of up to several hundred feet between the Gunnplexer and the board have been used with no problems. For long IF connection runs it is desirable to install a 30-MHz preamplifier at the Gunnplexer to prevent the long cable run from adversely affecting the system noise figure.

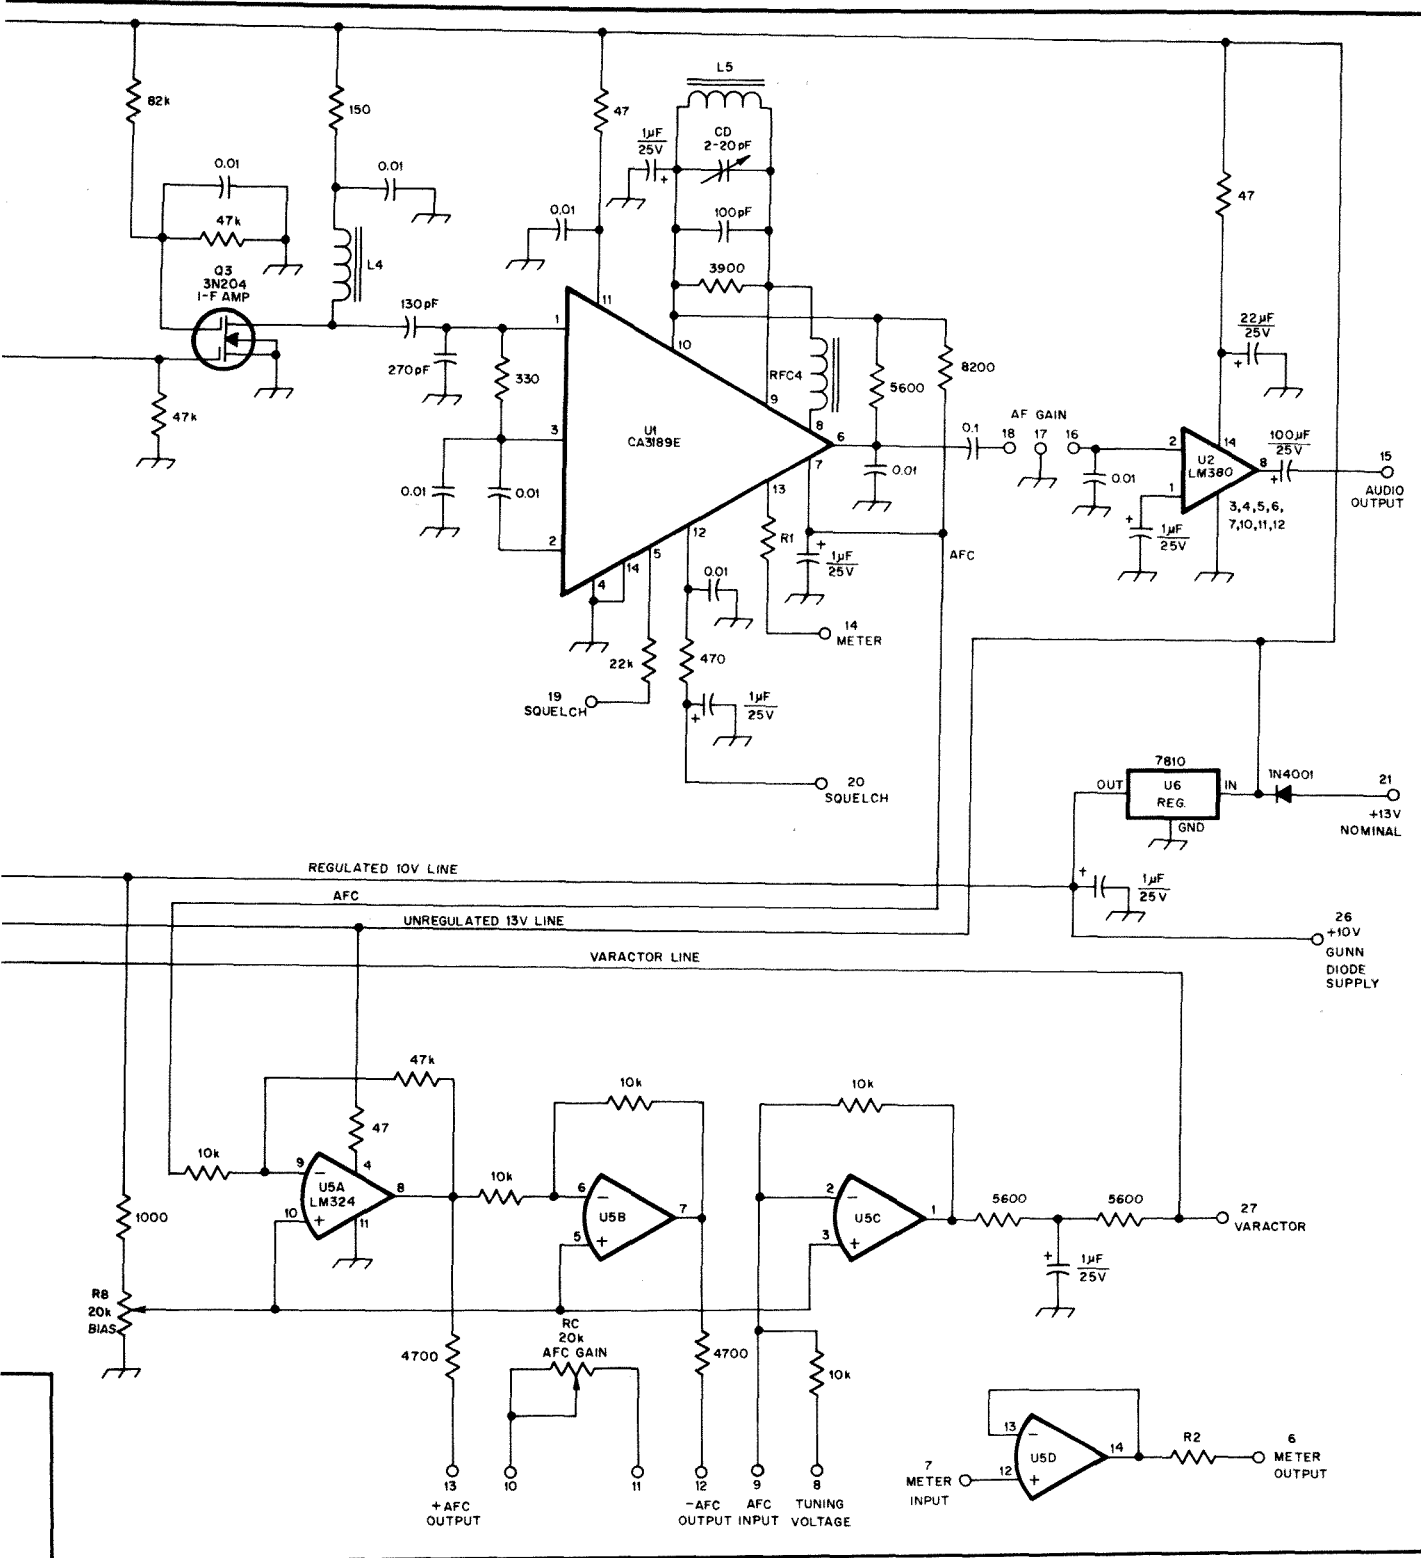

The Gunnplexer system is capable of complete duplex communications, so good

separation between the microphone and speaker is mandatory. The use of headphones for this type of communications is generally advisable.

#### Alignment

1) Connect a signal generator capable of delivering a 30-MHz signal to the IF input connection.

2) Adjust the output level of the

generator to a point where the signal-strength meter just begins to move up scale.

3) Adjust  $C_a$ ,  $C_b$  and  $C_c$  for maximum indication on the meter.

4) Temporarily disconnect the signal generator from the input.

5) Place S1 in the discriminator position.

6) While switching S3 between the + and - AFC positions, adjust  $R_b$  so that the same meter reading is obtained in both

switch positions. This reading should be mid scale on the discriminator meter.

7) Reconnect the signal generator to the input and center the signal in the receiver passband.

8) While switching S1 between the AFC ON and OFF positions, adjust  $C_d$  so that the same meter reading is obtained for both positions. This reading should be mid scale on the discriminator meter.

9) Adjust  $R_c$  for the desired AFC gain/locking range by shifting the signal-generator frequency away from the pass-band center.

10)  $R_c$  is adjusted while in communication with another station. Advance the level of this control to the point where distortion occurs. Back off the setting of the control to the point where distortion is no longer present.

# Antenna Projects

Since the dawn of Amateur Radio, hams have been fascinated by antennas. Almost every ham has built at least one antenna, be it a dipole for one of the HF bands or a directional antenna for a VHF frequency. Through the years

amateurs have tried countless possible configurations — everything from rain-gutter long wires, to balloon-supported wires, to full-size 80-meter beams. A quick scan of any of the ham bands will yield several discussions that attest to the popularity of antenna experimentation among amateurs.

This chapter presents projects for amateurs wishing to construct their own antennas. Related information may be found in Chapters 16 and 17. Chapter 37 tells how to get antennas into the air and keep them there safely.

## Construction of Wire Antennas

There are many different types of wire antennas. The virtues of each, and the formulas for computing the right length for the desired operating frequency, are well documented in Chapter 17. The purpose of this section is to offer information on the actual physical construction of wire antennas. Because the dipole, in one of its configurations (Fig. 1), is probably the most common amateur wire antenna, it is used in the following examples. However, the techniques described here to enhance the reliability and safety of your antenna installations apply to all wire antennas.

### Wire

Choosing the right type of wire for the project at hand is the key to a successful antenna — the kind that gets out like gangbusters and stays up in the face of a winter ice storm or a gusty spring wind storm. What gauge of wire to use is the first question to settle, and the answer depends on strength, ease of handling, cost, availability and visibility. Generally, antennas that are expected to support their own weight, plus the weight of the feed line, should be made from no. 12 wire. Horizontal dipoles, Zepps, some long wires and the like fall into this category. Antennas supported in the center, such as inverted-V dipoles and delta loops, may be made from lighter material, such as no. 14 wire — the minimum size called for in the National Electrical Code.

The type of wire to be used is the next important decision. Table 1 details several

popular wire styles and sizes. The strongest wire suitable for antenna service is copper-clad steel, also known as Copperweld®. The copper coating is necessary for RF service because steel is a relatively poor conductor. Practically all of the RF current is confined to the copper because of skin effect. Copper-clad steel is outstanding for permanent installations, but it can be dif-

ficult to work with. Kinking, which severely weakens the wire, is a constant threat when handling any solid conductor.

Solid-copper wire, either hard drawn or soft drawn, is another popular material. Easier to handle than copper-clad steel, solid copper is available in a wide range of sizes. It is generally more expensive, however, because it is all copper. Soft-

Fig. 1 — Examples of simple but effective wire antennas. A horizontal dipole is shown at A. The legs can be drooped to form an "inverted V," as shown at B. A sloping dipole (sloper) is illustrated at C. The feed line should come away from the sloper at 90° for best results. If the supporting mast is metal, there will be some directivity in the direction of the slope. The antennas at B and C provide vertical polarization and are predominantly omnidirectional if they are supported on a non-metallic mast.

Table 1

## Stressed Antenna Wire

American Wire Gauge	Recommended Tension <sup>1</sup> (pounds)		Weight (pounds per 1000 feet)	
	Copper-clad steel <sup>2</sup>	Hard-drawn copper	Copper-clad steel <sup>2</sup>	Hard-drawn Copper
4	495	214	115.8	126
6	310	130	72.9	79.5
8	195	84	45.5	50
10	120	52	28.8	31.4
12	75	32	18.1	19.8
14	50	20	11.4	12.4
16	31	13	7.1	7.8
18	19	8	4.5	4.9
20	12	5	2.8	3.1

<sup>1</sup>Approximately one-tenth the breaking load. Might be increased 50 percent if end supports are firm and there is no danger of ice loading.

<sup>2</sup>"Copperweld," 40 percent copper.

Fig. 2 — Various types of commercially made insulators.

Fig. 3 — Some ideas for homemade antenna insulators.

Fig. 4 — Some dipole center insulators have built-in SO-239 connectors. Others are designed for direct connection to the feed line.

drawn tends to stretch under tension, so periodic pruning of the antenna may be necessary in some cases.

Enamel-coated "magnet-wire" is a good choice for experimental antennas because it is easy to manage, and the coating protects the wire from the weather. Although it stretches under tension, the wire may be prestretched before final installation and adjustment. A local electric motor rebuilder might be a good source for magnet wire.

Hook-up wire, speaker wire or even ac lamp cord are suitable for temporary installations. Almost any copper wire may be used, as long as it is strong enough for the demands of the installation. Steel wire is a poor conductor and should be avoided. Aluminum may be suitable in some cases, although it is not usually very strong and is difficult to adequately connect a feed line to.

It matters not (in the HF region at least)

whether the wire chosen is insulated or bare. However, the wire should be either enameled or insulated to prevent corrosion. If exposed, the bare copper surface will corrode, causing a resistive loss in current, which flows only on the surface due to skin effect. If insulated wire is used, a 3 to 5% shortening beyond the standard  $468/f$  length will be required to obtain resonance at the desired frequency, because of the increased distributed capacitance resulting from the dielectric constant of the plastic insulating material. The actual length for resonance must be determined experimentally by pruning and measuring because the dielectric constant of the insulating material varies from wire to wire. Portions that might come into contact with humans or animals should be insulated to reduce the chance of shock or burns. Several suppliers of wire suitable for the projects in this chapter are listed in Chapter 35.

### Insulators

Wire antennas must be insulated at the ends. Generally, commercially available insulators are made from ceramic, glass or plastic. Some of the more common types are pictured in Fig. 2. Insulators like these are available from many Amateur Radio dealers. Radio Shack and local hardware stores are other possible sources.

In a pinch, acceptable homemade insulators may be fashioned from a variety of material including (but not limited to) acrylic sheet or rod, PVC tubing, wood, fiberglass rod or even stiff plastic from a discarded container. Fig. 3 shows some homemade insulators. Ceramic or glass insulators will usually outlast the wire, so they are highly recommended for a safe, reliable, permanent installation. Other materials may tear under stress or break down in the presence of sunlight. Many types of plastic do not weather well.

Many types of wire antennas require an insulator at the feed point. Although there are many ways to connect the feed line, there are few things to keep in mind. If you feed your antenna with coaxial cable, you have two choices. You can install an SO-239 connector on the center insulator and use a PL-259 on the end of your coax, or you can separate the center conductor from the braid and connect the feed line directly to the antenna wire. Although the latter method is initially less costly, the former method offers several advantages. Coaxial cable braid soaks up water like a sponge. If you do not adequately seal the antenna end of the feed line, water will find its way into the braid. Water in the feed line will lead to contamination, rendering the coax useless long before its normal lifetime is up. It is not uncommon for water to drip from the end of the coax inside the shack after a year or so of service if the antenna connection is not properly waterproofed. Use of a PL-259/SO-239 combination (or connector of your choice) makes the task of waterproofing connections much easier.

Fig. 5 — Details of the dipole antenna. The end insulator connection is shown at A, while B illustrates the center insulator. Part C illustrates the completed antenna.

Another advantage to using the PL-259/SO-239 combination is that feed line replacement is much easier, should that become necessary.

Whether you use coaxial cable, open-wire "ladder line" or plastic-encased transmitting-type twin lead to feed your antenna, an often-overlooked consideration is the mechanical strength of the connection. Wire antennas and feed lines tend to move a lot in the breeze, and unless the feed line is attached securely, the connection will weaken with time. The resulting failure can range from a frustrating intermittent electrical connection to a complete separation of feed line and antenna. Fig. 4 illustrates several different ways of attaching the feed line to the antenna.

#### Putting It Together

Fig. 5 shows some of the finer points of antenna construction. Although a dipole is used for the examples, the techniques il-

lustrated here apply to any type of wire antenna.

How well you put the pieces together is second only to the ultimate strength of the materials used in determining how well your antenna will work over the long term. Even the smallest details, such as how you connect the wire to the insulators (Fig. 5A), contribute significantly to antenna longevity. By using plenty of wire at the insulator and wrapping it tightly, you will decrease the possibility of the wire pulling loose in the wind. There is no need to solder the wire once it is wrapped. There is no electrical connection here, only mechanical. The high heat needed for soldering can anneal the wire, significantly weakening it at the solder point.

Similarly, the feed-line connection at the center insulator should be made to the antenna wires after they have been secured to the insulator (Fig. 5B). This way, you

will be assured of a good electrical connection between the antenna and feed line without compromising the mechanical strength. Do a good job of soldering the antenna and feed-line connections. Use a heavy iron or a torch, and be sure to clean the materials thoroughly before starting the job. Proper planning should allow you to solder indoors at a workbench, where the best possible joints may be made. Poorly soldered or unsoldered connections will become a headache as the wire oxidizes and the electrical integrity degrades with time. Besides degrading your antenna performance, poorly made joints can be a cause of TVI because of rectification.

If made from the right materials, the dipole illustrated in Fig. 5C should give the builder years of maintenance-free service — unless of course a tree falls on it! As you build your antenna, keep in mind that if you get it right the first time, you won't have to do it again for a long time.

# Construction of Beams and Vertical Monopoles

Most beams and verticals are made from sections of aluminum tubing that have been extruded or drawn. Compromise beams have been fashioned from less-expensive materials such as electrical conduit (steel) or bamboo poles wrapped with conductive tape or aluminum foil. The steel conduit is heavy, is a poor conductor and is subject to rust. Similarly, bamboo with conducting material attached to it will deteriorate rapidly in the weather. Aluminum tubing is by far the best material for building antennas in the HF and VHF regions. Copper or brass may be used in some VHF and UHF applications, and this idea is discussed later in this chapter.

Aluminum tubing comes in a variety of sizes, detailed in Table 2. Such tubing is available in many metropolitan areas. Dealers may be found in the Yellow Pages under "Aluminum." Tubing usually comes in 12-foot lengths, although 20-foot lengths

are available in some sizes. Your aluminum dealer will probably also sell aluminum plate in various thicknesses needed for boom-to-mast and boom-to-element connections.

Aluminum is rated according to its hardness. The most common material used in antenna construction is grade 6061-T6. This material is relatively strong and has good workability. In addition, it will bend without taking a "set," an advantage in antenna applications where the pieces are constantly flexing in the wind. The softer grades (5051, 3003, etc.) will bend much more easily, while harder grades (7075, etc.) are more brittle.

## Beam Elements

Beam elements are generally made from telescoping sections of aluminum tubing. The prime consideration when choosing tubing sizes is mechanical strength. Ob-

viously, a 66-foot-long 40-meter element would be made from much larger material than an 18-foot-long 10-meter element. Fig. 6 shows generic element designs for 10, 15 and 20-meter elements. The exact length of each element will depend on the electrical design.

Wall thickness is of primary concern when selecting tubing. It is of utmost importance that the tubing fits snugly where the element sections join. Sloppy joints will make a mechanically unstable antenna. The magic wall thickness is 0.058 in. For example (from Table 2), 1-in outside diameter (OD) tubing with a 0.058-in wall has an inside diameter (ID) of 0.884 in. The next smaller size of tubing, 7/8 in, has an OD of 0.875 in. The 0.009-in difference provides just the right amount of clearance for a snug fit.

Fig. 7 shows several methods of fastening antenna element sections to-

\*These sizes are extruded; all other sizes are drawn tubes. Shown here are standard sizes of aluminum tubing that are stocked by most aluminum suppliers or distributors in the United States and Canada.

Fig. 6 — Element designs for Yagi antennas. (Use 0.058-in-wall aluminum tubing except for end pieces where thinner-wall tubing may be used.)

Fig. 7 — Some methods of connecting telescoping tubing sections to build beam elements. See text for a discussion of each method.

gether. The slot and hose clamp method shown in Fig. 7A is probably the best for joints where adjustments are needed. Generally, one adjustable joint per element half is sufficient to tune the antenna. Stainless steel hose clamps (beware — some “stainless steel” models do not have a stainless screw and will rust) are recommended for longest antenna life.

Figs. 7B, 7C and 7D show possible fastening methods for joints that are not adjustable. At B, machine screws and nuts hold the elements in place. At C, sheet metal screws are used. At D, rivets secure the tubing. If the antenna is to be assembled permanently, rivets are the best choice. Once in place, they are permanent. They will never work free, regardless of vibration or wind. If aluminum rivets with aluminum mandrels are employed, they will never rust. Also, being aluminum, there is no danger of corrosion from interaction between dissimilar metals. If the antenna is to be disassembled and moved periodically, either B or C will work. However, if machine screws are used, take all possi-

ble precautions to keep the nuts from vibrating free. Use of lock washers, lock nuts and flexible adhesive such as silicon bathtub sealant will keep the hardware in place.

Use of a conductive grease at the element joints is essential for long life. Left untreated, the aluminum surfaces will oxidize in the weather, resulting in a poor connection. Some trade names for this conductive grease are Penetrox, Noalox and Dow Corning Molykote 41. Many electrical supply houses carry these products.

#### Boom Material

The boom size for a rotatable Yagi or quad should be selected to provide stability to the entire system. The best diameter for the boom depends on several factors, but mostly the element weight, number of elements and overall length. Tubing diameters of 1½ inches can easily support 3-element 10-meter arrays and perhaps a 2-element 15-meter system. For larger 10-meter antennas or for harsh weather conditions, and for antennas up to 3 ele-

Fig. 8 — A long boom needs both vertical and horizontal support. The crossbar mounted above the boom can support a double truss, which will help keep the antenna in position.

Fig. 9 — The boom-to-element plate at A uses muffer-clamp-type U-bolts and saddles to secure the round tubing to the flat plate. The boom-to-mast plate at B is similar to the boom-to-element plate. The main difference is the size of materials used.

ments on 20 meters or 4 elements on 15 meters, a 2-inch-diameter boom will be adequate. Two-inch-diameter booms should not be made any longer than 24 feet unless additional support is given to reduce both vertical and horizontal bending forces. Suitable reinforcement for a long 2-inch boom can consist of a truss or a truss and lateral support, as shown in Fig. 8.

A boom length of 24 feet is about the point where a 3-inch diameter begins to be very worthwhile. This dimension provides a considerable amount of improvement in overall mechanical stability as well as increased clamping surface area for element hardware. The latter is extremely important if heavy icing is commonplace and rotation of elements around the boom is to be avoided. Pinning an element to the boom with a large bolt helps in this regard. On the smaller diameter booms, however, the elements sometimes work loose and tend to elongate the pinning holes in both the element and the boom. After some time the elements shift their positions slightly (sometimes from day to day!) and give a ragged appearance to the system, even though this may not harm the electrical performance.

A 3-inch-diameter boom with a wall thickness of 0.065 inch is very satisfactory for antennas up in size to about a 5-element, 20-meter array that is spaced on a 40-foot-long boom. A truss is recom-

mended for any boom longer than 24 feet. One possible source for large boom material is irrigation tubing sold at farm supply houses.

### Putting It Together

Once you assemble your boom and elements, the next step is to fasten the elements to the boom securely and then fasten the boom to the mast or supporting structure. Fig. 9A shows the most practical method of attaching the elements to the boom. Of course, if the home constructor has access to a machine shop, there are any number of different ways to accomplish this. The size of the mounting plate will depend on the size of the boom and element materials used. Be sure to leave plenty of material on either side of the U-bolt holes. The U-bolts selected should be a snug fit for the tubing. If possible, purchase the

muffler-clamp type U-bolts that come with saddles.

The boom-to-mast plate shown in Fig. 9B is similar to the boom-to-element plate. The size of the plate and number of U-bolts used will depend on the size of the antenna. Generally, antennas for the bands up through 20 meters require only two U-bolts each for the mast and boom. Longer antennas for 15 and 20 (35-ft booms and up) and most 40-meter beams should have four U-bolts each for the boom and mast because of the torque that the long booms and elements exert as the antennas move in the wind. When tightening the U-bolts, be careful not to crush the tubing. Once the wall begins to collapse, the connection begins to weaken. Many aluminum suppliers sell  $\frac{1}{4}$ -in plate just right for this application. Often they will shear pieces to the

correct size on request. As with tubing, the relatively hard 6061-T6 grade is a good choice for mounting plates.

The antenna should be put together with good-quality hardware. Stainless steel is best for long life. Rust will attack plated steel hardware after a short while, making nuts difficult, if not impossible, to remove. If stainless muffler clamps are not available, the next best thing is to have them plated. If you can't get them plated, then at least paint them with a good zinc-chromate primer and a finish coat or two. Good-quality hardware is more expensive initially, but if you do it right the first time, you won't have to take the antenna down after a few years and replace the hardware. Also, when repairing or modifying an installation, nothing is more frustrating than fighting rusty hardware at the top of a tower.

## Portable Trap Dipoles

Vacationers, campers, sales people and QRPers take note! You need not carry a large multiband trap dipole afield if your transmitter is in the 150-W-output class, or lower. You can construct your own traps inexpensively with ordinary materials, and they can be made quite small without becoming poor performers. This project describes some easy techniques for fabricating homemade antenna traps. Additional hints are offered for keeping the bulk and weight of portable antennas within reason. Doug DeMaw, W1FB, originally presented this material in June 1983 *QST*.

### A Review of the Trap Concept

A "trap" is exactly what the term implies. It traps an RF signal to prevent it from passing beyond a specific point along an electrical conductor. At some other frequencies, however, it no longer acts as a trap, and permits the passage of RF energy.

An antenna trap is designed for a particular operating frequency, and there may be several traps in the overall system — each designed for a specific frequency. Therefore, a 40- through 10-meter trap dipole might contain traps for 10, 15, 20 and 30 meters. On 40 meters, all of the traps are "absorbed" into the system to become part of the overall 40-meter dipole. Owing to the loading effect of the traps, the 40-meter portion of the antenna will be

somewhat shorter than a full-size 40-meter dipole with no traps. The antenna bandwidth will be narrower when traps are used. Fig. 10A illustrates the general format for a multiband dipole.

A trap style of antenna is not as efficient as a full-size dipole. This is because there will always be some losses in the traps. But the losses in a well-designed system are usually so low that they are hard to measure by simple means. The losses represent a small trade-off for the convenience of being able to accommodate many ham bands with one radiator and a single feed line. Yagi antennas contain traps in the parasitic elements (directors and reflectors) as well as in the driven element. Therefore, a multielement antenna of that type may have as many as 12 traps.

### Electrical Characteristics

An antenna trap is a parallel-resonant L-C circuit. Therefore, it is similar to the tuned circuit in a transmitter or receiver. A resonator of this kind, if designed correctly, has a moderate Q and a fairly narrow bandwidth. This means the trap capacitor should have a high Q and the trap coil should contain wire that is reasonably large in cross section. These traits will help to reduce losses.

Fig. 10B shows the equivalent circuit for an antenna trap. Once this network is ad-

justed to resonance in the desired part of an amateur band, it will not be affected significantly by the attachment of the wires that comprise the antenna. A well-designed and -constructed trap should not change frequency by any great amount when the temperature or humidity around it varies. Therefore, it is important to use a stable capacitor, a rigid coil and some type of sealant.

### Mini Trap Using a Toroid Core

In an effort to scale down the size of antenna traps during a design exercise for a portable antenna, small toroidal cores on which to wind the coils were tried. Ferrite cores were ruled out because they aren't as stable as powdered-iron ones. Furthermore, the powdered-iron material has a much greater flux density than an equivalent-size ferrite core, which means that the core will not saturate as easily at moderate RF power levels.

Development work started with Micro-metals Corporation T50-6 toroids, which are sold by Amidon Associates, Palomar Engineers and RadioKit (see Chapter 35). The first effort resulted in a pair of very small 20-meter traps. A silver-mica capacitor was chosen for the parallel-tuned circuit. Ceramic capacitors were not used because of previous experiences with changes in value under temperature ex-

Fig. 10 — At A, a representation of a three-band trap dipole antenna. B shows the electrical equivalent of an antenna trap. The ac resistance is not shown. A suitable reactance value for the coil and capacitor is 200 ohms. C illustrates the physical arrangement for one of the toroidal L-C traps. Put spaghetti tubing over the capacitor leads to prevent them from shorting to the turns on the toroid. D shows one test method for finding the resonant frequency of a trap. Different points around the toroid will yield better dip indications. Experiment with the position of the dipper coil.

tremes; better results were obtained with dipped silver-mica units.

The rule of thumb for choosing the coil and capacitor values for traps is based on a reactance of approximately 200 ohms, although values up to 300 have also yielded good results. Using 200 ohms as the basis for the design, the calculated capacitor value was very close to a standard one — 56 pF for trap resonance at 14.100 MHz. This was obtained from

$$C (\mu\text{F}) = \frac{1}{2\pi f(\text{MHz})X_C}$$

Hence

$$C = \frac{1}{6.28 \times 14.1 \times 200} = 0.000564 \mu\text{F} (56 \text{ pF})$$

Since  $X_C$  and  $X_L$  are equal at resonance, the coil was calculated from

$$L (\mu\text{H}) = \frac{X_L}{2\pi f(\text{MHz})}$$

Hence

$$L = \frac{200}{6.28 \times 14.1} = 2.25 \mu\text{H} (\text{approx.})$$

The value of the coil will have to be adjusted slightly after the trap is assembled to allow for capacitor tolerance and stray capacitance, which accounts for the term "approximate."

The Amidon toroid tables were consulted to learn the  $A_L$  factor of a T50-6 core (½-inch-diameter toroid). The value is 40.

From this, the number of turns was calculated from

$$\text{Turns} = 100 \sqrt{L_{\mu\text{H}}/A_L}$$

Hence

$$\text{Turns} = 100 \sqrt{2.25/40} = 23.7$$

For practical reasons a 24-turn winding was used: A partial turn is not convenient on a toroid form.

The same procedure was used for the remaining traps in the antenna. The equations can be useful to those who have not previously designed resonant circuits or used toroidal cores.

#### Toroidal-Trap Adjustment

It's best to use the largest size wire that will fit easily on the toroid core. The stiffness of the heavier magnet wire will help to keep the coil turns in place, thereby minimizing detuning. This design used no. 24 enameled wire.

The capacitor leads and coil "pigtailed" should be kept as short as possible. Fig. 10C illustrates the layout. The leads at each end of the mica capacitor are soldered to the related coil leads before final adjustment is made.

A dip meter can be used to determine the resonant frequency of the trap, as shown in Fig. 10D. Although a prominent feature of a toroidal coil is the self-shielding characteristic, which makes it difficult for us to get ample coupling with a dip meter, it is possible to read a dip. By inserting the dip-meter coil into the area of the winding

gap on the tuned circuit (Fig. 10D) a dip can be obtained. By approaching the trap from different angles, it should be easy to find a spot where a dip can be read on the meter. Once the dip is found, back off the instrument until the dip is barely discernible (the minimum-coupling point). Monitor the dip-meter signal on a calibrated receiver to learn the resonant frequency of the trap.

Select a part of the related amateur band for trap resonance, perhaps the center of the frequency spread most often used. For example, set 20-meter traps for resonance at 14.025 MHz for 14.000 to 14.050 MHz. For phone-band coverage, 14.275 MHz is a good choice for the trap frequency. A compromise frequency for phone and CW operation would be 14.100 MHz. Owing to the trap Q, coverage of an entire band is not possible without having an SWR of 2:1 or greater at the band-edge extremes. The absolute bandwidth will depend on the trap Q and the Q of the antenna itself.

If the trap is not on the desired frequency, move the turns of the toroidal coil farther apart to raise the frequency. Push them closer together to lower the frequency. An alternative method for finding the trap resonance is shown in Fig. 11. The trap being tested is connected to terminals x and y. The coupling is very light in order to prevent the test-circuit capacitance from appearing in parallel with the trap. For this reason the coupling capacitors are only 2 pF. The station transmitter is adjusted for the lowest power output that will provide a reading on M1. The VFO is then swept

manually across the band. When the resonant frequency of the trap is located, the meter (M1) will deflect upward sharply, indicating resonance. Adjust the trap for a frequency that is approximately 5% lower than the desired one. This will compensate for the shunt capacitance presented by the 2-pF coupling capacitors.

When the coil turns are set in the correct manner, spread a bead of fast-drying epoxy cement across the turns on the two flat sides of the toroid. This will prevent unwanted position changes that could cause a shift in resonance later on from handling.

### Housing the Mini Trap

A 7/8-inch-OD PVC plumbing coupling, 1 1/4 inches long, will serve nicely as a housing for the toroidal traps. A ridge inside the couplings at the center can be filed out easily to provide clearance for the trap. A rat-tail file does the job quickly. Fig. 12A shows a breakaway view of how the trap is assembled. Slices of dowel rod are used for end plugs. A knot is tied in the antenna wire that enters the trap housing; this prevents strain on the trap coil.

After the antenna wire has been soldered to the trap at each end, add a layer of epoxy glue to the outer perimeter of one of the dowel plugs, then insert it into the PVC coupling until it is flush. Fill the coupling with noncorrosive sealant such as aquarium cement. Finally, place epoxy glue on the remaining end plug and insert it in the PVC coupling. Allow the trap to set for 48 hours, until the sealant has hardened. Fig. 12B is a photograph of a mini trap, along with a dipole center insulator made from a PVC T-coupling. The coupling is filled with sealant after the wires are soldered to the coaxial feed line. Long plugs are used to close the three open ends of the T connector. A closed nylon loop, made from strong spaghetti tubing, was fed through two small holes at the top of the T-coupling to permit erecting the dipole as an inverted V. A small eye bolt and nut could have been used instead.

There was a minor downward shift in trap resonance after the sealant hardened. Both 20-meter traps shifted roughly 30 kHz lower. No doubt this was caused by increased distributed capacitance across the coil turns with the sealant in place. This seemed to have no effect on the trap quality; it had a measured parallel resistance of 25 kΩ before and after encapsulation (using the laboratory RX meter for tests). Generally, anything greater than 10 kΩ is suitable for an antenna trap.

### Mini Coaxial-Cable Traps

Two very interesting articles concerning antenna traps appeared in the amateur literature during 1981.<sup>1,2</sup> Some advantages

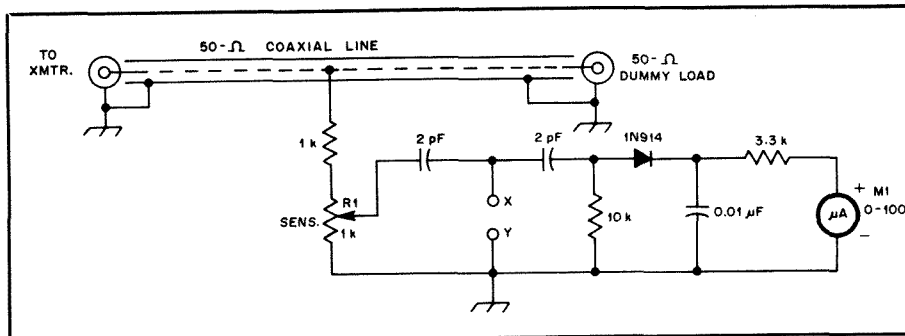

Fig. 11 — Test fixture suitable for checking trap resonance with the station transmitter. Use the least amount of power necessary for meter deflection.

Fig. 12 — A shows a breakaway view of a toroidal mini trap. The knots in the wire prevent stress on the tuned circuit. B illustrates a toroidal mini trap, an encapsulated toroid and a PVC T-coupling for use as a center insulator. RG-58 cable is shown in this example (see text).

over the usual coil/capacitor style of trap were described by the authors: (1) The traps were not especially frequency sensitive to changes in temperature and climate; (2) the coaxial trap offers greater effective bandwidth; and (3) parallel resistance is quite high — on the order of 50 kΩ.

The articles under discussion contained practical information about the use of RG-58 and RG-8 cable for the trap coils. A small, lightweight trap was desired, so miniature cable — RG-174 — was tried. A completed mini coaxial trap for 20 meters is shown in Fig. 13A.

The principle of operation is covered well by O'Neil (note 1). Since this article deals with the practical aspects of traps, we won't delve too deeply into the electrical characteristics of the coaxial trap. However, a diagram showing how it is hooked up is offered in Fig. 13C. A length of coaxial line is wound on a coil form, and the inner conductor at one end is attached to the outer conductor at the opposite end.

The distributed capacitance of the two conductors and the inductance of the coil combine to provide a resonant circuit. An acceptable Q results, and the trap can accommodate considerable RF voltage and current without being damaged. A parallel resistance of 50 kΩ was measured for the 20-meter trap of Fig. 13A. The bandwidth at the 10-kΩ points was somewhat greater than with the toroidal trap.

### Coaxial-Trap Assembly

PVC plumbing pipe, 5/8-in OD, is an acceptable and low-cost material for the coaxial traps. Fig. 13B shows a typical trap assembly. End plugs made from 1/2-inch wooden dowel fit snugly inside the PVC pipe. The completed trap contains a length of bus wire inside it for connecting the braid and center conductor of the cable together, as discussed earlier. The ends of the bus wire and the related cable ends are routed outside the PVC tubing through small holes, then soldered. Aquarium

<sup>1</sup>G. O'Neil, "Trapping the Mysteries of Trapped Antennas," *Ham Radio*, Oct. 1981, p. 10.

<sup>2</sup>R. Johns, "Coaxial Cable Antenna Traps," *QST*, May 1981, p. 15.

Fig. 13 — A shows completed 20-meter coaxial trap with miniature RG-174 coaxial cable. At B is a breakaway view of a coaxial trap. The illustration at C shows the electrical connections for a coaxial trap.

cement was applied to the sides of the wooden plugs before inserting them into the tubing. A layer of vinyl electrical tape can be wound over the coaxial coil if desired, although this should not be necessary. If weather protection is desired, a coating of exterior polyurethane varnish can be applied to the completed close-wound coil. This will keep the turns affixed in the desired position after final adjustment. Tune-up is carried out in the same manner as prescribed for the toroidal traps, using a dip meter or the test fixture described in Fig. 12.

The length of the coaxial cable used will have to be determined experimentally. The 20-meter coaxial trap contains 15 close-wound turns of RG-174 cable (36 inches, 89 pF) to provide resonance at 14.100 MHz. Final adjustment was done by moving the three outer turns at one end until the desired frequency was noted. The coil form for the 20-meter trap is 2½ inches long. The wooden end plugs are 3/8 inch thick. The inside of this trap is not filled with sealant, but it could be if desired. Avoiding the use of filler will make the traps lighter, thereby permitting the use of lighter-gauge wire for the antenna sections.

### Trap Performance

Both trap styles were subjected to RF power tests to determine whether they could handle the output of a typical 150-W class transceiver. A Bird wattmeter was connected between the trap and the transmitter. A 50-ohm dummy load was attached to the opposite end of the trap. Next, 40- and 80-meter RF energy was applied (in separate tests) gradually while the reflected power was observed, which, of course, was not conducive to providing an SWR of 1:1 with the trap in the line. Neither trap showed signs of heating or breakdown at power levels up to 150 W. A key-down period of five minutes was tried during the tests, using a linear amplifier adjusted for 150-W

output. Still no sign of power limitations. The SWR did not change under these conditions. Although the traps were not tested beyond 150 W, it's safe to conclude they could sustain substantially more power without damage. This may not be true of the toroidal trap.

### Toward a Lightweight Dipole

Having solved the problem of lightweight, small traps the next step was reducing the bulk of the remainder of the multiband dipole. The cost of materials was an important factor in the selection of wire and end insulators. Strong and light in weight, suitable wire is available from Radio Shack and similar outlets for use as speaker cable. It has a clear plastic outer covering and contains a no. 22 conductor. This roll yields 200 feet of wire because the parallel conductors can be pulled apart easily without harming the outer insulation. In addition to the insulation aiding the strength of wire portions of the antenna, it protects the copper wire from corrosion. This can be especially beneficial in areas where salt water and industrial pollutants affect the atmosphere.

Although RG-58 coaxial cable is less offensive in terms of loss per 100 feet than RG-174, the smaller cable is much more portable. Normally, a 50-foot length of feeder cable is adequate for portable work. Measured loss for 50 feet of RG-174 in decibels is as follows: 3.5 MHz — 1.19; 7.0 MHz — 1.42; 14.0 MHz — 1.67; 21 MHz — 1.93; 29 MHz — 2.0. Therefore, in a worst-case situation (10 meters), a 100-W power input to the cable would result in an antenna feed-point power of 63 W. RG-58, on the other hand, would have a 1-dB loss at 29 MHz, which would mean an antenna feed-point power of 79.4 W. This is not too significant when operating in the 50- to 150-W range, but it can be important when using a QRP rig with only a few watts or milliwatts of output power. The end insulators for the trap dipole discussed in this

article were fashioned from inch-long pieces of 5/8-inch-diameter PVC tubing. Holes were drilled to accommodate the dipole wires and nylon guy wires.

### Summary Comments

The overall length of any dipole section in a trap type of antenna will be less than if the dipole were cut for a single band without traps. The exception is the first dipole section after the feed point (out to the first set of traps). The following percentages (approximate) were typical in a coaxial-trap dipole built for use from 40 through 10 meters, compared to the length of a full dipole (100%) for each band: 10 meters — 100%; 15 meters — 92.4%; 20 meters — 88.8%; 40 meters — 83.6%. The shortening becomes more pronounced as the frequency is lowered, owing to the cumulative loading effects of the traps.

These percentages can be applied during initial structuring of the antenna. Starting with the highest band, the dipole sections for each frequency of interest are trimmed or lengthened for the lowest attainable SWR. After the exact dimensions are known, continuous lengths of wire can be used between the traps. This will add strength to the antenna by avoiding breaks in the speaker-wire insulation, if that type of conductor is used. The percentage reductions listed above are not necessarily applicable to antennas that use toroidal or other coil/capacitor traps. The wire diameter and insulation may also affect the final dimensions of the dipole.

For long-term installations, use some type of sealer (spar varnish or polyurethane) over the wooden end plugs of the traps. All trap holes need to be sealed securely to prevent moisture from building up inside them.

Miniature antenna traps and lightweight trap dipole antennas are practical and inexpensive to build. Try one during your next vacation or business trip.

# A Practical Two-Band Vertical

Fig. 14 shows a two-band trap vertical (20/15 meters) which can be collapsed to 39 inches for easy transportation on holidays, DXpeditions or camping trips. All of the tubing sections except B telescope together to make a compact package. The trap and base plate will be separate from the remainder of the antenna during storage or transport.

If portability is not a requirement, a single section of aluminum tubing can be used below the trap, although two sections (telescoping) are recommended to facilitate adjustment of the 15-meter portion of the system. Similarly, two telescoping tubes can be used above the trap (as shown) to permit adjustment for 20-meter operation.

Table 3 contains data on the starting lengths of the tubing sections, plus approximate dimensions for resonance on a variety of band pairings. Final adjustment is done for the lowest SWR attainable in the chosen part of each band (resonance). The adjustment must be done while the antenna is mounted for use with the ground system in place.

Fig. 15 shows the details of a simple trap with the tubing sections keyed to the nomenclature of Fig. 14. The ID of the PVC tubing is too small to accommodate the 1/2-inch-OD tubing. Therefore, a hacksaw is used to cut four slots at the ends of sections B and C so they will compress and fit into the PVC tubing. The wooden dowel plugs permit a tight bond when the hose clamps are compressed over the ends of the PVC tubing. Innovative builders can find other methods for mounting the trap in the antenna.

Copper straps G are slid into the PVC tubing to provide electrical contact with tubing sections B and C. The straps are bent (as shown) so they will fit under the hose clamps that affix the trap to the tubing. The trap capacitor and coil leads are soldered to the copper straps.

A thin layer of conductive silicon grease between the copper straps and the tubing sections will prevent undue oxidation. Similarly, the grease is applied to the mating surfaces of all of the tubing sections.

If coax cable is used for the trap capacitor, it can be taped (after soldering) to the upper tubing section (B) of Fig. 14. If a fixed-value transmitting capacitor is used, it should be located at the trap coil with stiff wire leads, which are soldered to copper tabs G. If a fixed-value capacitor is used, the trap can be brought to resonance by adjusting the coil turns. The exposed ends of the coax capacitor should be weather sealed.

## Ground System

If the antenna is mounted at ground

<sup>2</sup>Midband dimensions  $X_{c1}$ ,  $X_{L1}$  = 300 Ω

Fig. 14 — Details of the two-band trap vertical, which telescopes to 39 inches when dismantled. Stainless-steel hose clamps are used to hold the tubing sections together and to affix the trap to the tubing. A short length of flexible wire and a banana plug are connected to the base of the antenna for joining the antenna to the coax connector of Fig. 16.

level, section F of Fig. 14 should be as close to ground as possible. At least 20 radials are recommended. They need not be longer than 20 feet, and should be buried from 2 to 4 inches below the surface of the soil or lawn.

Fig. 15 — Close-up details of the trap construction and how it connects to tubing sections B and C of Fig. 14.

If an above-ground installation is planned, use at least four radials per band. The wires are cut to one-quarter wavelength for each of the bands, although some amateurs prefer to make them 5 percent longer than one-quarter wavelength to increase the antenna bandwidth slightly.

The slope of the above-ground radials can be changed to help provide a match to 50-ohm feed line. The greater the angle between the vertical element and the radial wires, the higher the feed impedance. The feed impedance will be approximately 30 ohms when the radials are at right angles to the vertical element. If such an installation is contemplated, a 1.6:1 broadband toroidal transformer can be used at the feed point to effect a matched condition.

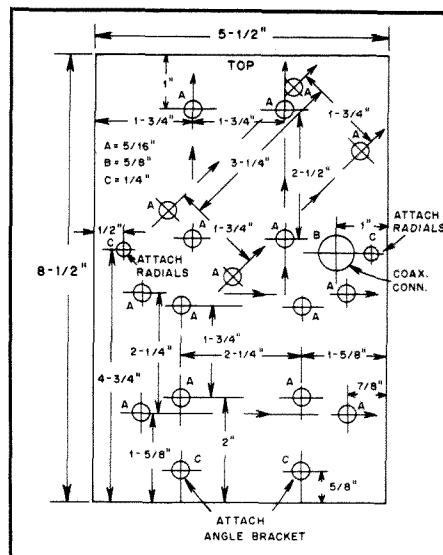

# Universal Mounting Plate

Fig. 16 illustrates a mounting plate that will satisfy a host of conditions one might encounter when operating from an unfamiliar place. The hole size and spacing will depend on the U-bolts or muffler clamps used with the antenna. The lower set of holes (except the bottom-most two) permit using a supporting mast that is either vertical or horizontal. The holes in the top half of the plate permit the antenna to be mounted vertically or at 45° angle. Hole B is for a female-to-female bulkhead connector. The feed line attaches to one side of the fitting, and the banana plug of Fig. 14 plugs into the center hole of the opposite end of the connector. This permits easy disconnection when disassembling the antenna. The radials are bolted to the two holes marked C, at the left and right center of the plate. The two holes (C) at the bottom of the plate are for bolting an iron or

aluminum angle stock to the plate. A second angle-stock piece is cut to the same size as the first and is used with the mounting hardware when it is convenient to clamp the mounting plate to a porch railing, window sill and so on. A pair of large C clamps can be used for this mounting technique.

The plate is made from 1/4-inch aluminum. Brass or copper material could be used equally well if available.

Fig. 16 — Layout details for a universal mounting plate. The hole sizes and spacing will depend on the type of U-bolts used (see text).

# Adapting Commercial Trap Verticals to the WARC Bands

The frequency coverage of a multiband vertical antenna can be modified simply by altering the lengths of the tubing sections and/or adding a trap. Several companies manufacture trap verticals covering 40, 20, 15 and 10 meters. Many amateurs roof-mount these antennas because an effective ground radial system isn't practical, to keep the children away from the antenna or to clear metal-frame buildings. On the three highest bands, the tubing and radial lengths are convenient for rooftop installations, but 40 meters sometimes presents problems. Prudence dictates erecting an antenna with the assumption that it will fall down. When the antenna falls, it and the radial system must clear any nearby power lines. Where this consideration rules out 40-meter operation, careful measurement may show that 30-meter dimensions will allow adequate safety. The antenna is resonated by pruning the tubing above the 20-meter trap and installing tuned radials.

Several new frequency combinations are possible. The simpler ones, 12/10, 17/15/10 and 40/30/20/15/10 meters, are shown in Fig. 17 applied to the popular ATV series of trap verticals manufactured by Cushcraft. Operation in the 30-meter band requires an additional trap — use Fig. 15 as a guide for constructing this component.

Fig. 17 — Modified dimensions for the ATV-series Cushcraft vertical antennas for some frequency combinations that include the WARC bands. The 30-meter trap inductor consists of 20 turns of no. 16 enameled wire close-wound on a 5/8-in-diameter Plexiglas rod. The capacitor is a 29 3/4-in length of RG-58 cable.

# A Three-Band Quad Antenna System

Quads have been popular with amateurs during the past few decades because of their light weight, their relatively small turning radius, and their unique ability to provide good DX performance when mounted close to the earth. A two-element three-band quad, for instance, with the elements mounted only 35 feet above the ground, will give good performance in situations where a triband Yagi will not. Fig. 18 shows a large quad antenna that can be used as a basis for design of either smaller or larger arrays.

Five sets of element spreaders are used to support the 3-element 20-meter, 4-element 15-meter, and 5-element 10-meter wire-loop system. The spacing between elements has been chosen to provide optimum performance consistent with boom length and mechanical construction. See Fig. 19. Each of the parasitic loops is closed (ends soldered together) and requires no tuning. All of the loop sizes are listed in Table 4 and are designed for a center frequency of 14.1, 21.1 and 28.3 MHz. Since quad antennas are broad-tuning devices, excellent performance is achieved in both CW and SSB segments of each band (with the possible exception of the very high end of 10 meters). Changing the dimensions to favor a frequency 200 kHz higher in each band to create a "phone" antenna is not necessary.

One question that comes up often is whether to mount the loops in a diamond or a square configuration. In other words, should one spreader be horizontal to the earth, or should the wire be horizontal to the ground (spreaders mounted in the fashion of an X)? From the electrical point of view, it is probably a trade-off. While the square configuration has its lowest point higher above ground than a diamond version (which may lower the angle of radiation slightly), the top is also lower than that of a diamond-shaped array. Some authorities indicate that separation of the current points in the diamond system gives

Fig. 18 — The assembled and installed three-band cubical-quad beam antenna.

Fig. 19 — Dimensions of the three-band cubical quad. See Table 4 for the dimensions of the lettered wires.

Table 4

Three-Band Quad Loop Dimensions

Band	Reflector	Driven Element	First Director	Second Director	Third Director
20 meters	(A) 72'8"	(B) 71'3"	(C) 69'6"	—	—
15 meters	(D) 48'6½"	(E) 47'7½"	(F) 46'5"	(G) 46'5"	—
10 meters	(H) 36'2½"	(I) 35'6"	(J) 34'7"	(K) 34'7"	(L) 34'7"

Letters indicate loops identified in Fig. 19.

slightly more gain than is possible with a square layout. It should be pointed out, however, that there never has been any substantial proof in favor of one or the other, electrically.

Spreader supports (sometimes called spiders) are available from many different manufacturers. The builder who is keeping the cost at a minimum should consider building his or her own. The expense is about half that of a commercially manufactured equivalent and, according to some authorities, the homemade arm supports described below are less likely to rotate on the boom as a result of wind pressure.

A 3-foot-long section of 1-inch-per-side steel angle stock is used to interconnect the pairs of spreader arms. The steel is drilled at the center to accept a muffler clamp of sufficient size to clamp the assembly to the boom. The fiberglass is attached to the steel angle stock with automotive hose clamps, two per pole. Each quad-loop spreader frame consists of two assemblies of the type shown in Fig. 20.

Fig. 20 — Details of one of two assemblies for a spreader frame. The two assemblies are joined to form an X with a muffler clamp mounted at the position shown.

# An Optimum-Gain Two-Band Yagi Array

If optimum performance is desired from a Yagi, the dual four-element array shown in Fig. 21 will be of interest. This antenna consists of four elements on 15 meters interlaced with the same number for 10. Wide spacing is used, providing excellent gain and good bandwidth on both bands. Each driven element is fed separately with 50-ohm coax; gamma-matching systems are employed. If desired, a single feed line can be run to the array and then switched by a remotely-controlled relay.

The element lengths shown in Fig. 21 are for the phone portions of the band,

Fig. 21 — The element lengths shown are for the phone sections of the bands. Table 5 provides the dimensions for CW frequencies.

These lengths are for 0.2- or 0.15-wavelength element spacing.

centered at 21,300 and 28,600 kHz. If desired, the element lengths can be changed for CW operation, using the dimensions given in Table 5. The spacing of the elements will remain the same for both phone and CW.

The elements are supported by commercially made U-bolt assemblies. Muffler clamps also make excellent element supports. The boom-to-mast support (Fig. 22) is also a manufactured item that is designed to hold a 2-inch-diameter boom and that can be used with mast sizes up to 2½ inches in diameter (Table 6). Another feature of this device is that it permits the beam to be tilted after it is mounted in place on the tower, providing access to the elements if they need to be adjusted once the beam has been mounted on the tower.

Fig. 22 — The boom-to-mast fixture that holds the two 12-foot boom sections together. The unit is made by Hy-Gain Electronics.

1	8	1 1/4	10A
1	6	7/8	4231

Two U-bolts, TV antenna to mast type, 1 variable capacitor, 150 pF maximum, any type, 1 plastic freezer container, approx. 5 x 5 x 5 inches, to house gamma capacitor.

Gamma rod, 3/8- to 1/2-inch diameter aluminum tubing, 36 inches long. (Aluminum curtain rod or similar.)

# Simple Antennas for HF Portable Operation

The typical portable HF antenna is a random-length wire flung over a tree and end-fed through a Transmatch. QRP Transmatches can be quite compact, but each additional piece of equipment necessary makes portable operation less attractive. The station can be simplified by using resonant impedance-matched antennas for the bands of interest. Perhaps the simplest antenna of this type is the half-wave dipole, center-fed with 50- or 75-ohm coax. Unfortunately, RG-58, RG-59 or RG-8 cable is heavy and bulky for backpacking, and the miniature cables such as RG-174 are too lossy. A practical solution to the coax problem is to use folded dipoles made from lightweight TV twin lead. The characteristic impedance of this type of dipole is near 300 ohms, but it can be transformed to a 50-ohm source or load by means of a simple matching stub.

Fig. 23 illustrates the construction method and important dimensions for the twin-lead dipole. A silver-mica capacitor is shown for the reactive element, but an open-end stub of twin lead can serve as well, provided it is dressed at right angles to the transmission line for some distance. The stub method has the advantage of easy adjustment of the system resonant frequency.

To preserve the balance of the feeder, a 1:1 balun must be used at the end of the feed line. In most applications the balance is not important, and the twin lead can be connected directly to a coaxial output jack, one lead to the center contact, and one lead to the shell. To preserve its low loss, the twin lead must be kept dry and free from bunching or coiling. Because of its higher

Fig. 23 — A twin-lead folded dipole makes an excellent portable antenna that is easily matched to 50-ohm stations.

impedance, a folded dipole exhibits a wider bandwidth than a single-conductor type. The antennas described here are not as broad as a standard folded dipole because the impedance transformation mechanism

is frequency selective. However, the bandwidth should be adequate. An antenna cut for 14.175 MHz, for example, will present an SWR of less than 2:1 over the entire 20-meter band.

# HF Mobile Antennas

The antenna is perhaps the most important item in the successful operation of a mobile installation. Mobile antennas, whether designed for single or multiband use, should be securely mounted to the automobile, as far from the engine compartment as possible (for reducing noise pickup), and should be carefully matched to the coaxial feed line connecting them to the transmitter and receiver. All antenna connections should be tight and weather-proof. Mobile loading coils should be protected from dirt, rain and snow if they are to maintain their Q and resonant frequency. The greater the Q of the loading coil, the better the efficiency, but the narrower the bandwidth of the antenna system.

Though bumper-mounted mobile antennas are favored by some, it is better to place the antenna mount on the rear deck of the vehicle, near the rear window. This locates the antenna high and in the clear, assuring less detuning of the system when the antenna moves to and from the car body. *Never use a base-loaded antenna on a bumper mount.*

The choice of base or center loading a mobile antenna has been a matter of controversy for many years. In theory, the center-loaded whip presents a slightly higher base impedance than does the base-loaded antenna. However, with proper impedance-matching techniques employed there is no discernible difference in performance between the two methods. A base-loading coil requires fewer turns of wire than one for center loading, and this is an electrical advantage because of reduced coil losses. A base-loaded antenna is more stable during wind loading and sway. If a homemade antenna system is contemplated, either system will provide good results, but the base-loaded antenna may be preferred for its mechanical advantages (Table 7).

## Loading Coils

There are many commercially built antenna systems available for mobile operation, and some manufacturers sell the coils as separate units. Air-wound coils of large wire diameter are excellent for use as loading inductors. Large Miniductor coils can be installed on a solid phenolic rod and used as loading coils. Miniductors, because of their turns spacing, are easy to adjust when resonating the mobile antenna and provide excellent Q. Phenolic-impregnated paper or fabric tubing of large diameter is suitable for making homemade loading coils. It should be coated with liquid fiberglass, inside and out, to make it weatherproof. Brass insert plugs can be installed in each end, their centers drilled and tapped for a standard 3/8 x 24 thread to accommodate the mobile antenna sections. After the coil winding is pruned to

**Table 7**

### Approximate Values for 8-foot Mobile Whip

#### Base Loading

f(kHz)	Loading L(μH)	RC(Q50) Ohms	RC(Q300) Ohms	RR Ohms	Feed R* Ohms	Matching L(μH)
1800	345	77	13	0.1	23	3
3800	77	37	6.1	0.35	16	1.2
7200	20	18	3	1.35	15	0.6

21,250	2.5	6.6	1.1	27.0	29	0.29

RC = Loading-coil resistance; RR = radiation resistance.

\*Assuming loading coil Q = 300, and including estimated ground-loss resistance.

Suggested coil dimensions for the required loading inductance are shown in a following table.

**Table 8**

### Suggested Loading-Coil Dimensions

Required L (μH)	No. Turns	Wire Size	Dia In	Length In
700	190	22	3	10
345	135	18	3	10
150	100	16	2½	10
77	75	14	2½	10
77	29	12	5	4¼
40	28	16	2½	2
40	34	12	2½	4¼
20	17	16	2½	1¼
20	22	12	2½	2¾
8.6	16	14	2	2
8.6	15	12	2½	3
4.5	10	14	2	1¼
4.5	12	12	2½	4
2.5	8	12	2	2
2.5	8	6	2-3/8	4½
1.25	6	12	1¾	2
1.25	6	6	2-3/8	4½

resonance (Table 8) it should be coated with a high-quality, low-loss compound to hold the turns securely in place and to protect the coil from the weather. Liquid polystyrene is excellent for this. Hobby stores commonly stock this material for use as a protective film for wall plaques and other artwork. Details for making a home-built loading coil are given in Fig. 24.

## Impedance Matching

Fig. 25 illustrates the shunt-fed method of obtaining a match between the antenna and the coaxial feed line. For operation on 75 meters with a center-loaded whip, L2 will have approximately 18 turns of no. 14 wire, spaced one wire thickness between turns, and wound on a 1-inch-diameter form. Initially, the tap will be approximately five turns above the ground end of L2. Coil L2 can be inside the car body, at the base of the antenna, or it can be located at the base of the whip, outside the car

Fig. 24 — Details for making a home-built mobile loading coil. A breakdown view of the assembly is given at A. Brass end plugs are snug-fit into the ends of the phenolic tubing, and each is held in place by four 6-32 brass screws. Center holes in the plugs are drilled and tapped for 3/8-24 thread. The tubing can be any diameter from 1 to 4 inches. The larger diameters are recommended. Illustration B shows the completed coil. Resonance can be obtained by installing the coil, applying transmitter power, then pruning the turns until the lowest SWR is obtained. Pruning the coil for maximum field-strength-meter indication will also serve as a resonance indication.

Fig. 25 — A mobile antenna using shunt-feed matching. Overall antenna resonance is determined by the combination of L1 and L2. Antenna resonance is set by pruning the turns of L1, or adjusting the top section of the whip, while observing the field-strength meter or SWR indicator. Then, adjust the tap on L2 for lowest SWR.

body. The latter method is preferred.

Since L2 helps determine the resonance of the overall antenna, L1 should be tuned to resonance in the desired part of the band with L2 in the circuit. The adjustable top section of the whip can be telescoped until a maximum reading is noted on the field-strength meter. The tap is then adjusted on L2 for the lowest reflected-power reading on the SWR bridge. Repeat these two adjustments until no further increase in field strength can be obtained; this point should coincide with the lowest SWR. The number of turns needed for L2 will have to be determined experimentally for 40- and 20-meter operation. There will be proportionately fewer turns required.

### Matching with an L Network

Any resonant mobile antenna that has a feed-point impedance less than the characteristic impedance of the transmission line can be matched to the line by means of a simple L network, as shown in Fig. 26. The network is composed of  $C_M$  and  $L_M$ . The required values of  $C_M$  and  $L_M$  may be determined from

$$C_M = \frac{\sqrt{R_A(Z_0 - R_A)}}{2\pi f \text{ (kHz)} R_A Z_0} \times 10^9 \text{ pF}$$

and

$$L_M = \frac{\sqrt{R_A(Z_0 - R_A)}}{2\pi f \text{ (kHz)}} \times 10^3 \mu\text{H}$$

where

$R_A$  = the antenna feed-point resistance

$Z_0$  = the characteristic impedance of the transmission line.

As an example, if the feed-point resistance is 20 ohms and the line is 50-ohm coaxial cable, then at 4000 kHz,

$$C_M = \frac{\sqrt{20(50 - 20)}}{(6.28)(4000)(20)(50)} \times 10^9$$

$$= \frac{\sqrt{600}}{(6.28)(4)(2)(5)} \times 10^4$$

$$= \frac{24.5}{251.2} \times 10^4 = 975 \text{ pF}$$

$$L_M = \frac{\sqrt{20(50 - 20)}}{(6.28)(4000)} \times 10^3$$

$$= \frac{\sqrt{600}}{25.12} = \frac{24.5}{25.12} = 0.97 \mu\text{H}$$

The chart of Fig. 27 shows the capacitive reactance of  $C_M$  and the inductive reactance of  $L_M$  necessary to match various antenna impedances to 50-ohm coaxial cable. The chart assumes the antenna element has been resonated.

In practice,  $L_M$  need not be a separate inductor. Its effect can be duplicated by adding an equivalent amount of inductance to the loading coil, regardless of whether the loading coil is at the base or at the center of the antenna.

### Adjustment

In adjusting this system, at least part of  $C_M$  should be variable, the balance being made up of combinations of fixed mica capacitors in parallel as needed. A small, one-turn loop should be connected between  $C_M$  and the chassis of the car, and the loading coil should then be adjusted for resonance at the desired frequency as indicated by a dip meter coupled to the loop at the base. Then the transmission line should be connected, and a check made with an SWR indicator connected at the transmitter end of the line.

With the line disconnected from the antenna again,  $C_M$  should be readjusted and the antenna returned to resonance by readjustment of the loading coil. The line should be connected again, and another check made with the SWR bridge. If the SWR is less than it was on the first trial,  $C_M$  should be readjusted in the same direction until the point of minimum SWR is found. Then the coupling between the line and the transmitter can be adjusted for proper loading.

It will be noticed from Fig. 27 that the inductive reactance varies only slightly over the range of antenna resistances likely to be encountered in mobile work. Therefore, most of the necessary adjustment is in the capacitor. The one-turn loop at the base

Fig. 26 — A whip antenna may also be matched to coax line by means of an L network. The inductive reactance of the L network can be combined in the loading coil, as indicated at the right.

Fig. 27 — Curves showing inductive and capacitive reactances required to match a 50-ohm coax line to a variety of antenna resistances.

should be removed at the conclusion of the adjustment and slight compensation made at the loading coil to maintain resonance.

For manufactured loading coils that have no means for either adjusting or tapping into the inductance, here is a simple L-network matching method that requires no series inductor, and needs only a measurement of SWR to determine the value of the shunt matching capacitor  $C_M$ . By extending the whip slightly beyond its natural resonant length, the series induc-

Fig. 28 — A capacitive hat can be used to improve the performance of base- or center-loaded whips. A solid metal disc can be used in place of the skeletal disc shown here.

tance required for the L network appears in the feed-point impedance. At the correct length, the resulting parallel reactance component,  $X_L$ , causes the parallel resistance component,  $R_A$ , to equal the feed line characteristic impedance,  $Z_0$  ohms. The match is accomplished by cancelling the parallel inductive reactance component,  $X_L$ , with shunt capacitor  $C_M$ , of equal but opposite reactance.

To perform the matching operation, first resonate the antenna at the desired frequency by adjusting the whip length for minimum SWR without the capacitor. The approximate value of  $X_L$  with the whip lengthened to make  $R_A$  equal to  $Z_0$ , may now be found from

$$X_L = Z_0 \times \sqrt{\text{SWR}/(\text{SWR} - 1)}$$

where SWR is that obtained at resonance. The reactance,  $X_C$ , of the shunt matching capacitor  $C_M$  is the negative of  $X_L$ . The capacitance of  $C_M$  may be determined for the desired frequency,  $f$ , in MHz from

$$C_M = 1 \times 10^6 / 2\pi f X_C \text{ pF.}$$

Form a capacitor,  $C_M$ , from a combina-

tion of fixed-mica capacitors in parallel, as needed, and connect the combination across the antenna input terminals as shown in Fig. 26. Finally, increase the whip length in small increments until the minimum SWR is reached — it should be very low.

If a lower SWR is desired, a trimmer capacitor may be added to  $C_M$ , and by alternate adjustment of trimmer and whip length, a perfect 1:1 match can be obtained. Once  $C_M$  has been established for a given band, the antenna can then be matched at other frequencies in the band by simply adjusting the whip length for minimum SWR. If an inductive rather than a capacitive shunt element is preferred, replace the capacitor with an inductor having the same absolute value of reactance, and shorten the whip instead of lengthening it from the natural resonant length.

#### Top-Loading Capacitance

Because the coil resistance varies with the inductance of the loading coil, the resistance can be reduced, beneficially, by reducing the number of turns on the coil. This can be done by adding capacitance to that portion of the mobile antenna that is *above* the loading coil (Fig. 28). To achieve resonance, the inductance of the coil is reduced proportionally. Capacitive hats can consist of a single stiff wire, two wires or more, or a disc made up from several wires like the spokes of a wheel. A solid metal disc can also be used. The larger the capacitive hat, in terms of surface area, the greater the capacitance. The greater the capacitance, the smaller the amount of inductance needed in the loading coil for a given resonant frequency.

There are two schools of thought concerning the attributes of center-loading and base-loading. It has not been established that one system is superior to the other, especially in the lower part of the HF spectrum. For this reason both base and center-loading schemes are popular. Capacitive-hat loading is applicable to either system. Since more inductance is required for

center-loaded whips to make them resonant at a given frequency, capacitive hats should be particularly useful in improving their efficiency.

The capacitance that is increased by the hat is the total antenna-to-ground and vehicle capacitance, which provides the path for the antenna currents to return to the generator or transmitter. To obtain optimum effectiveness, the hat should be placed at the top of the whip, which may require special mechanical considerations to keep the whip upright with wind loading. If the hat is large enough to be effective, only a negligible increase in capacitance will result from extending the whip above the hat. It is important to know that with center-loaded whips, the hat actually becomes more detrimental than helpful if placed directly above the loading coil. This incorrect placement causes an undesirable increase in hat-to-coil capacitance, which adds to the distributed capacitance of the coil, lowering the Q and increasing the coil resistance — just the opposite of the hat's intended purpose. Although often seen in this position, it is usually because of the mistaken notion that increased radiation results from the lower resonant SWR obtained by this incorrect placement. Such a placement does reduce feed-line load mismatch and SWR at resonance, but for the wrong reason. The total antenna-circuit load resistance is increased, bringing it closer to the 50-ohm impedance of the feed line. However, since this increase in load resistance is from the increased coil resistance, and not from an increase in radiation resistance, reducing the SWR in this manner increases the loss instead of the radiation. It is also for this reason that loading coils of the highest Q should be favored above the coils of lower Q used by some manufacturers to enable them to advertise a lower SWR. The rule to follow then, is that, since the coil with the highest Q has the lowest loss resistance, the coil that yields the highest SWR at resonance (without any matching circuitry) will produce the greatest radiation.

# The VHF, UHF Yagi

The small size of VHF and, especially, UHF arrays opens up a wide range of construction possibilities. Finding components is somewhat difficult for home constructors of ham gear, but it should not hold back antenna work. Radio and TV distributors have many useful antenna parts and materials. Hardware stores, metal suppliers, lumber yards, welding-supply and plumbing-supply houses and even junkyards should not be overlooked. With a little imagination, the possibilities are endless.

## Boom Materials

Wood is very useful in antenna work. It is available in a great variety of shapes and sizes. Rug poles of wood or bamboo make fine booms. Round wood stock (doweling) is found in many hardware stores in sizes suitable for small arrays. Square or rectangular boom and frame materials can be cut to order in most lumber yards if they are not available from the racks in suitable sizes.

There is no RF voltage at the center of a half-wave dipole or parasitic element, so no insulation is required in mounting elements that are centered in the support, whether the latter is wood or metal. Wood is good for the framework of multibay arrays for the higher bands, as it keeps down the amount of metal in the active area of the array.

Wood used for antenna construction should be well-seasoned and free of knots or damage. Available materials vary, depending on local sources. Your lumber dealer can help you better than anyone else in choosing suitable materials. Joining wood members at right angles is often done advantageously with gusset plates. These can be made of thin outdoor-grade plywood or Masonite. Round materials can be handled in ways similar to those used with metal components, with U clamps and with other hardware.

Metal booms have a small "shorting effect" on elements that run through them. With materials sizes commonly employed, this is not more than one percent of the element length, and may not be noticeable in many applications. It is just perceptible with 1/2-inch tubing booms used on 432 MHz, for example. Formula lengths can be used as given, if the matching is adjusted in the frequency range one expects to use. The center frequency of an all-metal array will tend to be 0.5 to 1 percent higher than a similar system built of wooden supporting members.

## Element Materials

Antennas for 50 MHz need not have elements larger than 1/2-inch diameter, though up to 1 inch is used occasionally. At 144 and 220 MHz the elements are usually 1/8 to 1/4 inch in diameter. For 420

MHz, elements as small as 1/16 inch in diameter work well, if made of stiff rod. Aluminum welding rod, 3/32 to 1/8 inch in diameter is fine for 420-MHz arrays, and 1/8 inch or larger is good for the 220-MHz band. Aluminum rod or hard-drawn wire works well at 144 MHz. Very strong elements can be made with stiff-rod inserts in hollow tubing. If the tubing is slotted and tightened down with a small clamp, the element lengths can be adjusted experimentally with ease.

Sizes recommended above are usable with formula dimensions given in Table 9. Larger diameters broaden frequency response; smaller ones sharpen it. Much smaller diameters than those recommended will require longer elements, especially in 50-MHz arrays.

## Element and Boom Dimensions

Tables 9 through 12 list element and boom dimensions for several Yagi configurations for operation on 50, 144, 220 and 432 MHz. These figures are based on information contained in the *National Bureau of Standards Technical Note 688*, which offers element dimensions for maximum-gain Yagi arrays as well as other types of antennas. The original information provides various element and boom diameters. The information shown in the tables represents a highly condensed set of antenna designs, however, making use of standard and readily available material. Element and boom diameters have been chosen so as to produce lightweight, yet very rugged, antennas. Fig. 29 shows various methods of attaching the elements to the boom.

Since these antennas are designed for maximum forward gain, the front-to-back pattern ratios may be a bit lower than those for some other designs. Ratios on the order of 15 to 25 dB are common for these antennas and should be more than adequate for most installations. Additionally, the patterns are quite clean, with the side lobes well suppressed. The driven-element lengths for the antennas represent good starting-point dimensions. The type of feed system used on the array may require longer or shorter lengths, as appropriate. Full details of the various methods for feeding a Yagi array are given in Chapter 17 and in the *ARRL Antenna Book*. Generally speaking, a balanced feed system is preferred in order to prevent pattern skewing and the possibility of unwanted side lobes, which can occur with an unbalanced feed system.

Element spacing for the various arrays is presented in Fig. 30 in terms of the wavelength of the boom, as noted in the first column of Tables 9 through 12. The 0.4, 0.8, 2.2 and 3.2-wavelength boom antennas have equally spaced elements for both reflector and directors; 1.2- and 4.2-wavelength boom antennas have dif-

Fig. 29 — Various techniques for mounting Yagi elements.

ferent reflector and director spacings. As all of the antenna parameters are inter-related, changes in element diameter, boom diameter and element spacing will require that a new design be worked out. As the information presented in the *NBS Technical Note 688* is straightforward, the serious antenna experimenter should have no difficulty designing antennas with different dimensions from those presented in the tables. For antennas with the same element and boom diameters, but for different frequencies within the band, standard scaling techniques may be applied.

## Stacking Yagis

Where suitable provision can be made for supporting them, two Yagis mounted one above the other and fed in phase may be preferable to one long Yagi having the same theoretical or measured gain. The pair will require a much smaller turning space for the same gain, and their lower radiation angle can provide interesting results. On long ionospheric paths a stacked pair occasionally may show an *apparent* gain much greater than the 2 to 3 dB that can be measured locally as the gain due to stacking.

Optimum spacing for Yagis of five elements or more is one wavelength, but this may be too much for many builders of 50-MHz antennas to handle. Worthwhile results can be obtained with as little as one half-wavelength (10 feet) and 5/8 wavelength (12 feet). The difference be-

tween 12 and 20 feet may not be worth the added structural problems involved in the wider spacing, at 50 MHz, at least. The closer spacings give lower measured gain,

but the antenna patterns are cleaner than will be obtained with one-wavelength spacing. The extra gain realized with wider spacings is usually the objective on 144

MHz and higher bands, where the structural problems are not severe.

One method for feeding two 50-ohm antennas, as might be used in a stacked Yagi array, is shown in Fig. 31. The transmission lines from each antenna to the common feed point must be equal in length and an odd multiple of a quarter wavelength. This line acts as an impedance transformer and raises the feed impedance of each antenna to 100 ohms. When the two antennas are connected in parallel at the coaxial "T" fitting, the resulting impedance is close to 50 ohms.

# A 5-Element Yagi for 50 MHz

The antenna described here (Figs. 32 through 36) was designed from information contained in Table 9 and Fig. 30. This antenna has a theoretical gain of 11.3 dB over an isotropic antenna (dBi) and should exhibit a front-to-back ratio of roughly 18 dB. The pattern is quite clean, with side lobes well suppressed. A hairpin matching system is used, and if the dimensions are followed closely no adjustment should be necessary. The completed antenna is rugged, yet lightweight, and should be easy to install on any tower or mast.

## Mechanical Details

Construction details of the antenna are given in Figs. 33 and 34. The boom of the antenna is 17 feet long and is made from a single piece of 2-inch aluminum irrigation tubing that has a wall thickness of 0.047 inch. Irrigation tubing is normally supplied in 20 foot sections, so several feet may be removed from the length.

Elements are constructed from 3/4-inch-OD aluminum tubing of the 6061-T6 variety, with a wall thickness of 0.058 inch. Each element, with the exception of the driven element, is made from a single length of tubing. The driven element is split in the center and insulated from the boom to provide a balanced feed system. The reflector and directors have short lengths of 7/8-inch aluminum tubing telescoped over the center of the elements for reinforcement purposes. Boom-to-element clamps (Fig. 36) were fashioned from 3/16-inch-thick aluminum-plate stock, as shown in the photographs.

Two muffler clamps hold each plate to the boom, and two U-bolts affix each element to the plate. Exact dimensions of the plate are not critical, but should be great enough to accommodate the two muffler clamps and two U-bolts. The element and clamp structure may seem to be a bit over-engineered. However, the antenna is

Fig. 33 — Dimensional drawing of the 5-element, 50-MHz Yagi antenna described in the text.

Fig. 34 — Detailed drawing of the feed system used with the 50-MHz Yagi. Phasing-line lengths are: for cable with 0.80 velocity factor — 7 ft 10-3/8 in; for cable with 0.66 velocity factor — 6 ft 5-3/4 in.

Fig. 32 — Photograph of the 5-element, 50-MHz Yagi. A 432-MHz beam is mounted above.

Fig. 35 — Closeup of the driven element and feed system. The phasing line is coiled and taped to the boom.

designed to withstand the severe weather conditions common to New England. This antenna has withstood many wind storms and several ice storms, and no maintenance has been required.

The driven element is mounted to the boom on a Bakelite plate of similar dimension to the reflector and director element-to-boom plates. A piece of 5/8-inch Plexiglas rod, 12 inches in length, is inserted into each half of the driven element. The Plexiglas piece allows the use of a single clamp

Fig. 36 — Photograph of the element-to-boom clamp. U-bolts are used to hold the element to the plate, and 2-inch plated muffler clamps hold the plates to the boom.

on each side of the element and also seals the center of the elements against moisture. Self-tapping screws are used for connection to the driven element. A length of  $\frac{1}{4}$ -inch polypropylene rope is inserted into each element, and end caps are placed on the elements. The rope damps element vibrations that could lead to element or hardware fatigue.

#### Feed System

Details of the feed systems are shown in Figs. 34 and 35. A bracket fashioned from a piece of scrap aluminum is used to mount the three SO-239 connectors to the driven

element plate. A half-wavelength phasing line connects the two element halves, providing the necessary 180-degree phase difference between them. The "hairpin" is connected directly across the element halves. It should be noted that the exact center of the hairpin is electrically neutral and may be fastened to the boom or allowed to hang. Phasing-line lengths are: for cable with 0.80 velocity factor —  $7' 10\frac{3}{8}"$ ; for cable with 0.66 velocity factor —  $6' 5\frac{3}{4}"$ . It will be noted that the driven element is the shortest element in this array. While this may seem a bit unusual, it is necessary with the hairpin matching system.

## A Portable 144-MHz Antenna for Emergency Use

Much local emergency work is done on VHF FM these days. VHF FM equipment lends itself to portable operation, and many amateurs have 2-meter capability at home, in their cars or portable with hand-held transceivers. But how does an emergency-powered station located in a remote shelter filled with evacuees communicate with the emergency operations center (EOC) when the repeater has been knocked off the air? Effective simplex communications are needed when that high-altitude repeater antenna is not available. One way to get the needed ERP for simplex communications is the addition of a high-power amplifier. A power amplifier, however, requires a healthy chunk of battery power, and in an emergency situation battery power may be at a premium.

In an emergency situation with many shelters in operation, some as many as 25 miles away, communications are usually controlled from a central EOC. The shelters need not hear each other, but they all must be able to communicate reliably with that EOC. Often, these communications are conducted with the help of a repeater; however, in an emergency, the repeater may not always be operational. At times, the stations in remote shelters may have to maintain simplex contact with the EOC for several days using very low transmitter power to conserve whatever battery power is available. Some type of gain antenna that can be set up in a hurry solves the problem of getting enough ERP to maintain communications while not drawing excessive battery power. Dick Jansson, WD4FAB, describes here the portable Yagi

that the Orange County, Florida, ARES group developed for 2-meter communications with its remote emergency shelters.

The antenna illustrated in Figs. 37 through 39 fits in a package no larger than  $4 \times 8 \times 48$  inches (the original shipping cartons taped together) and can be set up in less than five minutes. The antenna can be as high as 10 feet off the ground. Fig. 37 shows the erected antenna (not extended to its full 10-foot height). Fig. 38 shows the pieces as they were shaken out of the boxes. This antenna system was made from commercially manufactured items with a few simple additions to speed assembly. It is stored partially assembled and requires no tools for setup.

The antenna itself is a Cushcraft model A147-4 four-element Yagi. The screws and brackets that hold the elements to the boom are premounted to the elements with the original hardware supplied with the antenna. A visit to the local hardware store yielded wing nuts that allow speedy assembly of the prepared brackets and elements to the boom. To reduce setup time to a minimum, each element is color coded with spray paint, and the boom is coded accordingly. No instructions are necessary. The operator just shakes the parts out of the box, matches up the colors, and

Fig. 37 — The complete emergency antenna takes less than five minutes to set up, yet provides gain equal to a power amplifier without draining battery power. The driven element doubles as a boom support, and the tripod mount is a standard photographic-studio light stand.

Fig. 38 — The antenna breaks down into several compact pieces for transportation. Element hardware is preassembled and color coded for speedy assembly.

tightens down the wing nuts by hand. Assembly is as simple as possible.

The antenna driven element is made from tubing, rather than rod. This is a distinct advantage, because the driven element can double as an extension of the light stand, providing support for the boom. This arrangement further reduces weight and parts count. A section of tapered tubular-fiberglass fishing-rod stock that was purchased from a local sporting goods shop insulates the driven element tip from the support mast. The rod was selected so that one end slipped snugly into the driven element, and the other slipped over the support mast. See Fig. 39. A small piece of 3/8-inch-OD wooden dowel was jammed about 6 inches inside the large end of the fiberglass tubing to keep the tubing from sliding too far over the support stand tip.

Use a fiberglass section that is at least 12 inches long to keep the metal mast out of the field of the beam. This practice will help you to avoid unwanted coupling between the metal parts (which would detune the antenna).

The antenna support is a photographic-studio light stand that folds into a compact package for transportation. The support shown here is a Smith-Vector model S3. This model and other similar stands are available at many camera stores. It is used without modification.

Be sure your antenna kit has a 15-foot length of RG-58 coaxial cable with the necessary connectors for your equipment. The setup illustrated here uses a PL-259 connector for the antenna end, while the transceiver end is equipped with a UG-88 BNC connector.

Fig. 39 — Details of the driven-element-to-support mount.

This antenna adds significant range to a hand-held transceiver that normally uses a "rubber-duck" antenna, and you'll be surprised at the increase in your reliable communications range.

# A 15-Element Yagi for 432 MHz

This 432-MHz Yagi antenna was designed using the information shown in Table 12 and Fig. 30. The theoretical gain for this antenna is 16.3 dBi, with a front-to-back pattern ratio of approximately 22 dB. The pattern is very sharp and quite clean, as would be expected from a well-tuned array of this size. Four of these antennas in a "box" or "H" array would serve well for terrestrial work, while eight would make a respectable EME system. The completed antenna is shown in Fig. 40.

## Mechanical Details

Dimensions for the antenna are given in Figs. 41 and 42. The boom of the antenna is made from a length of 1-inch aluminum tubing. Each of the elements is mounted through the boom, and only the driven element is insulated. Auveco 8715 external retaining rings secure each of the parasitic elements in place. These rings are available at most hardware supply houses. Consult your local telephone company Yellow Pages for a hardware dealer near you.

The driven element is insulated from the boom by a length of 1/2-inch Teflon rod. The length of rod is drilled to accept the 1/4-inch-thick aluminum tubing driven element. A press fit was used to secure the Teflon piece in the boom of the antenna. An exact fit can be achieved by drilling the hole slightly undersized and enlarging the hole with a hand reamer, a small amount at a time. Should the hole turn out to be oversized, a small amount of RTV (silicone seal) can be used to secure the Teflon in place. Although it wasn't tried with this antenna, it should be possible to use a driven element that is not insulated from the boom. Small changes in the position of the matching rods and/or clamps might be necessary.

Fig. 40 — The completed 15-element Yagi for 432 MHz, ready for installation atop the tower.

Details of the feed system are shown in Fig. 42. This is a form of the "T" match, where the driven element is shortened from its resonant length to provide the necessary capacitance to tune out the reactance of the matching rods. With this system no variable capacitors are required, as in the more conventional T-match systems used at HF. This is a definite plus in terms of

antenna endurance in harsh-weather environments.

The center pin of the UG-58A N-type connector attaches to one of the matching rods. A half wavelength of 50-ohm, foam-dielectric cable is used to provide the 180-degree phase shift from one half of the element to the other. An alternative to the large and cumbersome cable used here

Fig. 41 — Dimensional drawing of the 15-element Yagi for 432 MHz. The balance point of the antenna is between the fifth and sixth director. The antenna was designed from the information presented in Table 12 and Fig. 30 of this chapter.

would be the miniature copper Hardline with Teflon dielectric material, such as RG-401.

Each of the matching rods is secured to two threaded steatite standoffs at the center of the antenna. These standoffs provide tie points for the ends of the phasing lines, the center pin of the coaxial connector as well as the ends of the matching rods. Solder lugs are used for each of the connections for easy assembly or disassembly. The clamps that connect the matching rods to the driven element are constructed from pieces of aluminum measuring  $\frac{1}{4} \times \frac{1}{2} \times 1\text{-}5/16$  inches. These pieces are drilled and slotted so when the screws are tightened the pieces will compress slightly to provide a snug fit. Alternatively, simple clamps could be fashioned from strips of aluminum.

### Adjustment

If the dimensions given in the drawings are followed closely, little adjustment should be necessary. If adjustment is necessary, as indicated by an SWR greater than 1.5 to 1, move the clamps a short distance along the driven element. Keep in mind that the clamps should be located equidistant from the center of the boom.

Fig. 42 — Detailed drawing of the feed system used with the Yagi. A small copper plate is attached to the coaxial-connector plate assembly for connection of the phasing line braid. As indicated, the braid is soldered to the plate. A coat of clear lacquer or enamel is recommended for waterproofing the feed system.

## The VHF Quagi

First described by K6YNB in April 1977 *QST*, the quagi has become a very popular antenna for use on 144 MHz and above. The long-boom quagi was presented by K6YNB/N6NB in February 1978 *QST*.

### How to Build a Quagi

There are a few tricks to quagi building. The designer has mass produced as many as 16 in one day. Table 13 gives the dimensions for an 8-element quagi, while Table 14 gives the dimensions for a long-boom, 15 element, 432-MHz version.

The boom is *wood* or any other nonconductor (e.g., fiberglass). If a metal boom is used, a new design and new element lengths will be required. Many VHF antenna builders go wrong by failing to follow this rule: If the original uses a metal boom, use the same size and shape metal boom when you duplicate it. If it calls for a wooden boom, use a nonconductor. Many amateurs dislike wood booms, but in a salt-air environment they outlast aluminum

**Table 13**

Boom — 1 × 2-inch × 12-ft Douglas fir, tapered to 5/8 inch at both ends.

Driven element — No. 12 TW copper-wire loop in square configuration, fed at center bottom with

type N connector and 52-ohm coax.

Reflector — No. 12 TW copper-wire loop, closed at bottom.

Directors — 1/8-inch rod passing through boom.

**Fig. 43** — A close-up view of the feed method used on a 432-MHz quagi. This arrangement produces an excellent SWR and an actual measured gain in excess of 13 dB over an isotropic antenna with a 4-foot 10-inch boom! The same basic arrangement is used on lower frequencies, but wood may be substituted for the Plexiglas spreaders. The boom is 1/2-inch exterior plywood.

(and surely cost less). Varnish the boom for added protection.

The 2-meter version is usually built on a 14-foot 1 × 3 inch boom, with the boom cut down to taper it to 1 inch at both ends. Clear pine is best because of its light weight, but construction-grade Douglas fir works well. At 220 MHz, the boom is under 10 feet long and most builders use 1 × 2 or (preferably) 3/4 by 1 1/4-inch pine molding stock. On 432 MHz the boom must be 1/2-inch thick or less. Most builders use strips of 1/2-inch exterior plywood for 432.

The quad elements are supported at the current maxima (the top and bottom, the latter beside the feed point) with Plexiglas or small strips of wood. The quad elements are made of no. 12 copper wire, commonly used in house wiring. Some builders may elect to use no. 10 wire on 144 MHz and no. 14 wire on 432 MHz, although this will change the resonant frequency slightly. Solder a type-N connector (an SO-239 is

often used at 2 meters) at the midpoint of the driven element bottom side, and close the reflector loop.

The directors are mounted through the boom. They can be made of almost any metal rod or wire of about 1/8-inch diameter. Welding rod or aluminum clothesline wire will work well if straight. (The designer used 1/8-inch stainless-steel rod secured from an aircraft surplus store.)

A TV-type U-bolt mounts the antenna on a mast. The author uses a single machine screw, washers and nut to secure the spreaders to the boom so the antenna can be quickly "flattened" for travel. In permanent installations two screws are recommended.

#### Construction Reminders

Here are a couple of hints based on the experiences of some who have built the quagi. First, remember that at 432 MHz even a 1/8-inch measuring error will

degrade performance. Cut the loops and elements as carefully as possible. No precision tools are needed, but be careful about accuracy. Also, make sure to get the elements in the right order. The longest director goes closest to the driven element.

Finally, remember that a balanced antenna is being fed with an unbalanced line. Fig. 43 shows details of the feed system on the 432-MHz quagi. Every balun the designer tried introduced more losses than the feed imbalance problem. Some builders have tightly coiled several turns of the feed line near the feed point to limit radiation further down the line. In any case, the feed line should be kept at right angles to the antenna. Run it from the driven element directly to the supporting mast and then up or down perpendicularly for best results.

## Helical Antenna for 432 MHz

Polarization is described as "horizontal" or "vertical," but these terms have no meaning once the reference of the earth's surface is lost. Many propagation factors can cause polarization change: reflection or refraction, passage through magnetic fields (Faraday rotation) and satellite rolling, for example. Polarization of VHF waves is often random, so an antenna capable of accepting any polarization is useful. Circular polarization, generated with helical antennas or with crossed elements fed 90 degrees out of phase, has this quality.

The circularly polarized wave, in effect, threads its way through space, and it can be left- or right-hand polarized. These polarization "senses" are mutually exclusive, but either will respond to any plane polarization. A wave generated with right-hand polarization comes back with left-hand, when reflected from the moon, a fact to be borne in mind in setting up EME circuits. The same applies with satellite circuits. Stations communicating on direct paths should have the same polarization sense.

Both senses can be generated with crossed dipoles, with the aid of a switchable phasing harness. With helical arrays, both senses are provided with two antennas, wound in opposite directions.

The eight-turn helix of Fig. 44 is designed for 432 MHz, with left-hand polarization.

Fig. 44 — An eight-turn 432-MHz helical array, wound from aluminum clothesline wire. Left-hand polarization is shown. Each turn is one wavelength, with a pitch of 0.25 wavelength. Feed is with 50-ohm coax, through an 84-ohm Q section.

It is made from 213 inches of aluminum clothesline wire, including 6 inches that is used for cutting back to adjust the feed impedance.

Each turn is one wavelength long, and the pitch is about 0.25 wavelength. Turns are stapled to the wooden supports, which should be waterproofed with liquid fiberglass or exterior varnish. The reflecting screen is one wavelength square, with a type-N coaxial fitting soldered at its center, for connection of the required coaxial Q section.

The nominal impedance of a helical antenna is 140 ohms, calling for an 84-ohm matching section to match to a 50-ohm line. This can be approximated with copper tubing of 0.4-inch inside diameter, with no. 10 inner conductor, both 6½ inches long. With the antenna and transformer connected, apply power and trim the outer end of the helix until the reflected power approaches zero.

The support arms are made from sections of 1 × 1-inch wood and are each 60 inches long. The spacing between them is 8¼ inches outer dimension. The screen of the antenna in Fig. 44 is tacked to the support arms for temporary use. A wooden framework for the screen would provide a more rugged antenna structure. The theoretical gain of an eight-turn helical is approximately 14 decibels. Where both right- and left-hand circularity are desired, two antennas can be mounted on a common framework, a few wavelengths apart, and wound for opposite senses.

## VHF Quarter-Wavelength Vertical Monopole

Ideally, the VHF vertical monopole should be installed over a perfectly flat plane reflector to assure uniform omnidirectional radiation. This suggests that the center of the automobile roof is the best place to mount it. Alternatively, the flat portion of the auto rear-trunk deck can be used, but will result in a directional pattern because of car-body obstruction.

Fig. 45 illustrates at A and B how a Millen high-voltage connector can be used as a roof mount for a 144-MHz whip. The hole in the roof can be made over the dome light, thus providing accessibility through the upholstery. RG-59 and matching section L, Fig. 45C, can be routed between the car roof and the ceiling upholstery and brought into the trunk compartment, or down to the dashboard of the car. Some operators install an SO-239 coax connector on the roof for mounting the whip. The method is similar to that of Fig. 45.

Fig. 45 — At A and B, an illustration of how a quarter-wavelength vertical antenna can be mounted on a car roof. The whip section should be soldered into the cap portion of the Millen connector, then screwed to the base socket. This handy arrangement permits removing the antenna when desired. Epoxy cement should be used at the two mounting screws to prevent moisture from entering the car. Diagrams C and D are discussed in the text.

## 2-Meter, 5/8-Wavelength Vertical

Perhaps the most popular vertical antenna for FM mobile and fixed-station use is the 5/8-wavelength vertical. Compared to a 1/4-wavelength vertical, it has some gain over a dipole. Additionally, the so-called "picket fencing" type of flutter that results when the vehicle is in motion is greatly reduced when a 5/8-wavelength radiator is employed.

This style of antenna is suitable for mobile or fixed-station use because it is small, omnidirectional and can be used with radials or solid-plane ground (such as is afforded by the car body). If radials are used, they need be only 1/4 wavelength or slightly longer. A 5 percent increase in length over 1/4 wavelength is suggested for the radial wires or rods.

### Construction

The antenna shown here is made from low-cost materials. Fig. 46A and B show the base coil and aluminum mounting plate. The coil form is a piece of low-loss solid rod, such as Plexiglas or phenolic. The dimensions for this and other parts of the antenna are given in Fig. 47. A length of brazing rod is used as the whip section.

The whip should be 47 inches long. However, brazing rod comes in standard 36-inch lengths, so it is necessary to solder an 11-inch extension to the top of the whip. A piece of no. 10 copper wire will suffice. Alternatively, a stainless-steel rod can be purchased to make a 47-inch whip. Shops that sell CB antennas should have such rods for replacement purposes on base-loaded antennas. The limitation one can expect with brazing rod is the relative fragility of the material, especially when the threads are cut for screwing the rod into the base-coil form. Excessive stress can cause the rod to break where it enters the coil form. The problem is complicated somewhat in this design by the fact that a spring is not used at the antenna mounting point. Innovators can find all manner of solutions to these problems by changing the physical design and using different materials when constructing the overall antenna. The main purpose of this description is to provide dimensions and tune-up data.

The aluminum mounting bracket must be shaped to fit the car with which it will be used. The bracket can be used to effect a "no-holes" mount. The inner lip of the vehicle trunk (or hood for front mounting) can be the point where the bracket attaches by means of no. 6 or no. 8 sheet-metal screws. The remainder of the bracket is bent so that when the trunk lid or car hood is raised and lowered, there is no contact between the bracket and the moving part. Details of the mounting unit are seen in Fig. 47 at B. A 14-gauge metal thickness (or greater) is recommended for best rigidity.

There are 10½ turns of no. 10 or no. 12

(A)

(B)

Fig. 46 — (A) A photograph of the 5/8-wavelength vertical base section. The matching coil is affixed to an aluminum bracket that screws onto the inner lip of the car trunk. (B) The completed assembly. The coil has been wrapped with vinyl electrical tape to prevent dirt and moisture from degrading performance.

copper wire wound on the 3/4-inch-diameter coil form. The tap on L1 is placed approximately four turns below the whip end. A secure solder joint is imperative.

### Tune-Up

After the antenna has been affixed to the vehicle, insert an SWR indicator in the 50-Ω transmission line. Turn on the 2-meter transmitter and experiment with the coil-tap placement. If the whip section is 47

Fig. 47 — Structural details for the 2-meter antenna are provided at A. The mounting bracket is shown at B and the equivalent circuit is given at C.

inches long, an SWR of 1:1 can be obtained when the tap is at the right location. As an alternative to this method of adjustment, place the tap at four turns from the top of L1, make the whip 50 inches long and trim the whip length until an SWR of 1:1 is secured. Keep the antenna free of conductive objects or human bodies during tune-up, as conductive objects will detune the antenna and spoil the match. This antenna was described more completely in June 1979 QST, page 15.

# A 5/8-Wavelength 220-MHz Mobile Antenna

This antenna, shown in Figs. 48 and 49, was developed to fill the gap between a homemade 1/4-wavelength mobile antenna and a commercially made 5/8-wavelength model. There have been other antennas made using modified CB models. This still presents the problem of cost in acquiring the original antenna. The major cost in this setup is the whip portion, which can be any tempered rod that will spring easily.

## Construction

The base insulator portion is constructed of 1/2-inch Plexiglas rod. A few minutes work on a lathe was sufficient to shape and drill the rod. The bottom 1/2-inch of the rod is turned down to a diameter of 3/8 inch. This portion will now fit into a PL-259 UHF connector. A hole, 1/8-inch diameter, is drilled through the center of the rod. This hole will contain the wires that make the connections between the center conductor of the connector and the coil tap. The connection between the whip and the top of the coil is also run through this opening. A stud is force-fitted into the top of the Plexiglas rod. This allows the whip to be detached from the insulator portion.

The coil should be wound initially on a

Fig. 48 — Photograph of the 220-MHz, 5/8-wavelength mobile antenna. The bottom end of the coil is soldered to the coaxial connector.

form slightly smaller than the base insulator. When the coil is transferred to the Plexiglas rod it will keep its shape and will not readily move. After the tap point has been determined, a longitudinal hole is drilled into the center of the rod. A no. 22 wire can then be inserted through the center of the insulator into the connector. This method is also used to attach the whip to the top of the coil. After the whip has been fully assembled, a coating of epoxy cement

Fig. 49 — Diagram of the 220-MHz mobile antenna.

is applied. It seals the entire assembly and provides some additional strength. During a full winter's use there were no signs of cracking or mechanical failure. The adjustment procedure is the same as for the 2-meter antenna just described.

# Ground-Plane Antennas for 144, 220 and 420 MHz

For the FM operator living in the primary coverage area of a repeater the ease of construction and low cost of a quarter-wavelength ground-plane antenna make it an ideal choice. Three different types of construction are detailed in Figs. 50 through 53; the choice of construction method will depend on the materials at hand and the desired style of antenna mounting.

The 2-meter model shown in Fig. 50 uses a flat piece of sheet aluminum, to which the radials are connected with machine screws. A 45-degree bend is made in each of the radials. This bend can be made with the aid of an ordinary bench vise. An SO-239 chassis connector is mounted at the center of the aluminum plate with the threaded part of the connector facing down. The vertical portion of the antenna is made of no. 12 copper wire soldered directly to the center pin of the SO-239 connector.

The 220-MHz version, Fig. 51, uses a slightly different technique for mounting

and sloping the radials. In this case the corners of the aluminum plate are bent down at a 45-degree angle with respect to the remainder of the plate. The four radials are held to the plate with matching machine screws, lockwashers and nuts. A mounting tab has been included in the design of this antenna as part of the aluminum base. A compression-type hose clamp could be used to secure the antenna to a mast. As with the 2-meter version the vertical portion of the antenna is soldered directly to the SO-239 connector.

A very simple method of construction, shown in Figs. 52 and 53, requires nothing more than an SO-239 connector and some 4-40 hardware. A small loop, formed at

Fig. 50 — These drawings illustrate the dimensions for the 146-MHz ground-plane antenna. The radials are bent down at a 45-degree angle.

Fig. 51 — Here is the dimensional information for the 220-MHz ground-plane antenna. The corners of the aluminum plate are bent down at a 45-degree angle rather than bending the aluminum rod as in the 146-MHz model. Either method is suitable for these antennas.

one end of the radial, is used to attach the radial directly to the mounting holes of the coaxial connector. After the radial is fastened to the SO-239 with 4-40 hardware, a large soldering iron or propane torch is used to solder the radial and the mounting hardware to the coaxial connector. The radials are bent to a 45-degree angle and the vertical portion is soldered to the center pin to complete the antenna. The antenna can be mounted by passing the feed line through a mast of  $\frac{3}{4}$ -inch ID plastic or

aluminum tubing. A compression hose clamp can be used to secure the PL-259 connector, attached to the feed line, in the end of the mast. Dimensions for the 146, 220 and 440-MHz bands are given in Fig. 52.

If these antennas are to be mounted outside it is wise to apply a small amount of RTV sealant or similar material around the area of the center pin of the connector to prevent water from entering the connector and coax line.

Fig. 52 — Simple ground-plane antenna for the 146, 220 and 440-MHz bands. The vertical element and radials are  $\frac{3}{32}$ - or  $\frac{1}{16}$ -inch brass rod. Although  $\frac{3}{32}$ -inch rod is preferred for the 2-meter antenna, 10- or 12-gauge copper wire can also be used.

Fig. 53 — A 440-MHz ground-plane antenna constructed using only an SO-239 connector, 4-40 hardware and  $\frac{1}{16}$ -inch brass rod.

switches. Q2 forces the audio-output impedance high when no keyboard switches are depressed, preventing the encoder from loading the transmitter mic input. Q4 and Q5 are operated as a Darlington pair, keying the transmitter push-to-talk (PTT) line when a keyboard switch is pressed. A single-package Darlington pair was originally used in this application, but its saturated collector voltage was high enough to prevent transmitter keying in some transceivers. Substituting discrete transistors solved the problem. Q2 and Q4 are driven by Q3, which is turned on by pulses from pin 7 of U1 when a keyboard switch is depressed.

U1 requires a 5-volt supply for proper operation. This is provided by the 470-ohm resistor and 1N4733 Zener diode, D1. With the exception of Q4, the remainder of the encoder circuit was also designed to operate from a 5-volt supply.

The length of time the transmitter remains keyed after a keyboard switch is released is determined by the 47- $\mu$ F capacitor connected to the collector of Q3. On the prototype unit, a value of 47  $\mu$ F provided a delay of just over one second. If you prefer a longer drop-out time, increase the value of this capacitor. Lowering its value will decrease drop-out time.

### Construction and Testing

The prototype was built on a piece of perforated board, but a PC board is preferable. A parts-placement guide for a commercially available circuit board is shown in Fig. 2. U1 should be installed in a socket. The 0.001- $\mu$ F disc capacitors connected to the base of Q4 and collector of Q5 should be installed as near the transistors as possible. Their function is to bypass RF from the transmitter, which can cause Q4 and Q5 to latch up in the keyed position.

A few simple checks will tell whether the circuit is functioning properly. The following tests may be performed before connecting the encoder to the radio, using only a 12-volt power supply, a high-impedance dc voltmeter and a scope, if one is available.

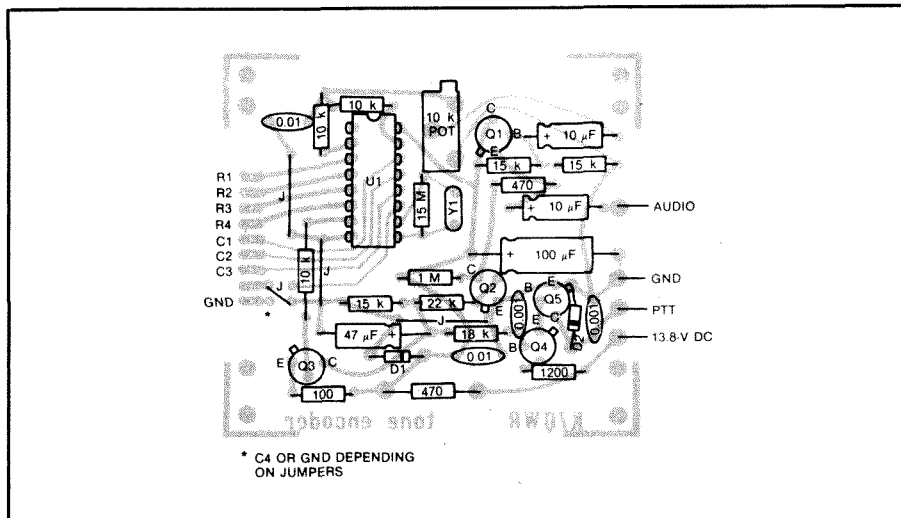

Fig. 2 — If the circuit board is used, this parts overlay will guide you when installing components. Circuit boards are available from Lea Engineering, 1230 E. Layola Dr., Tempe, AZ 85282. A full-size etching pattern can be found at the back of this book.

First ensure that D1 is regulating the encoder supply voltage at  $+5.1 \text{ V dc} \pm 10$  percent. U1 may be damaged if more than 6 volts is applied to pin 16.

The two operating states for the encoder are (1) no keyboard buttons depressed and (2) one or more buttons depressed. Connect the 12-V dc supply and measure the voltage at the test points shown on the schematic diagram. Voltages measured should be in accordance with those shown.

If any voltages are incorrect, look for wiring errors. If the collector voltage of Q2 is not at least 4 volts with no buttons pressed, the problem may be a leaky transistor at Q1 or Q2. If a scope is available it may be used to inspect the audio output. Pressing any one button should produce a two-tone signal, while depressing any two buttons simultaneously should produce a single tone.

### Installation

The electrical portion of the installation simply involves running four wires from the

encoder to the transceiver: +12 V, ground, push-to-talk (PTT) and audio output. Shielded audio cable is recommended for the audio output, which is connected to the transceiver mic input. The PTT lead is connected to the hot side of the mic PTT switch. The encoder PTT circuit is designed for rigs with an antenna relay coil connected to the +12 V bus and the PTT switch. The switch grounds the cold side of the relay coil during transmit. Ensure that your rig has this type of PTT circuit and that the relay coil draws less than 300 mA. Most of the popular VHF and UHF FM rigs have this type of PTT circuit. The mechanical details of the installation are left to the discretion of the builder.

Since the encoder will not load the audio system it should not be necessary to change the setting of any transmitter mic-level controls. Adjust only R1 in the encoder for proper tone deviation. The prototype unit has provided excellent performance on both a Tempo VHF/One 2-meter rig and a Kenwood TR-8300 UHF rig.

# A Simple DTMF Decoder

A Touch Tone® (dual-tone, multi-frequency, or DTMF) decoder can be a valuable link to a remotely controlled device, such as the phone patch in a repeater. Tone decoders of the past were rather large and unstable because they were constructed from discrete tone comparators such as the NE567. The '567 scheme also required rather expensive capacitors to keep the frequency even remotely accurate over a wide temperature range. Recently, Silicon Systems, Inc. introduced a new line of tone decoder ICs. They are hybrid devices, containing an audio filter, time base, tone decoders and TTL-compatible output drivers all on the same chip. Cost wise, it is less expensive to use the SSI IC as

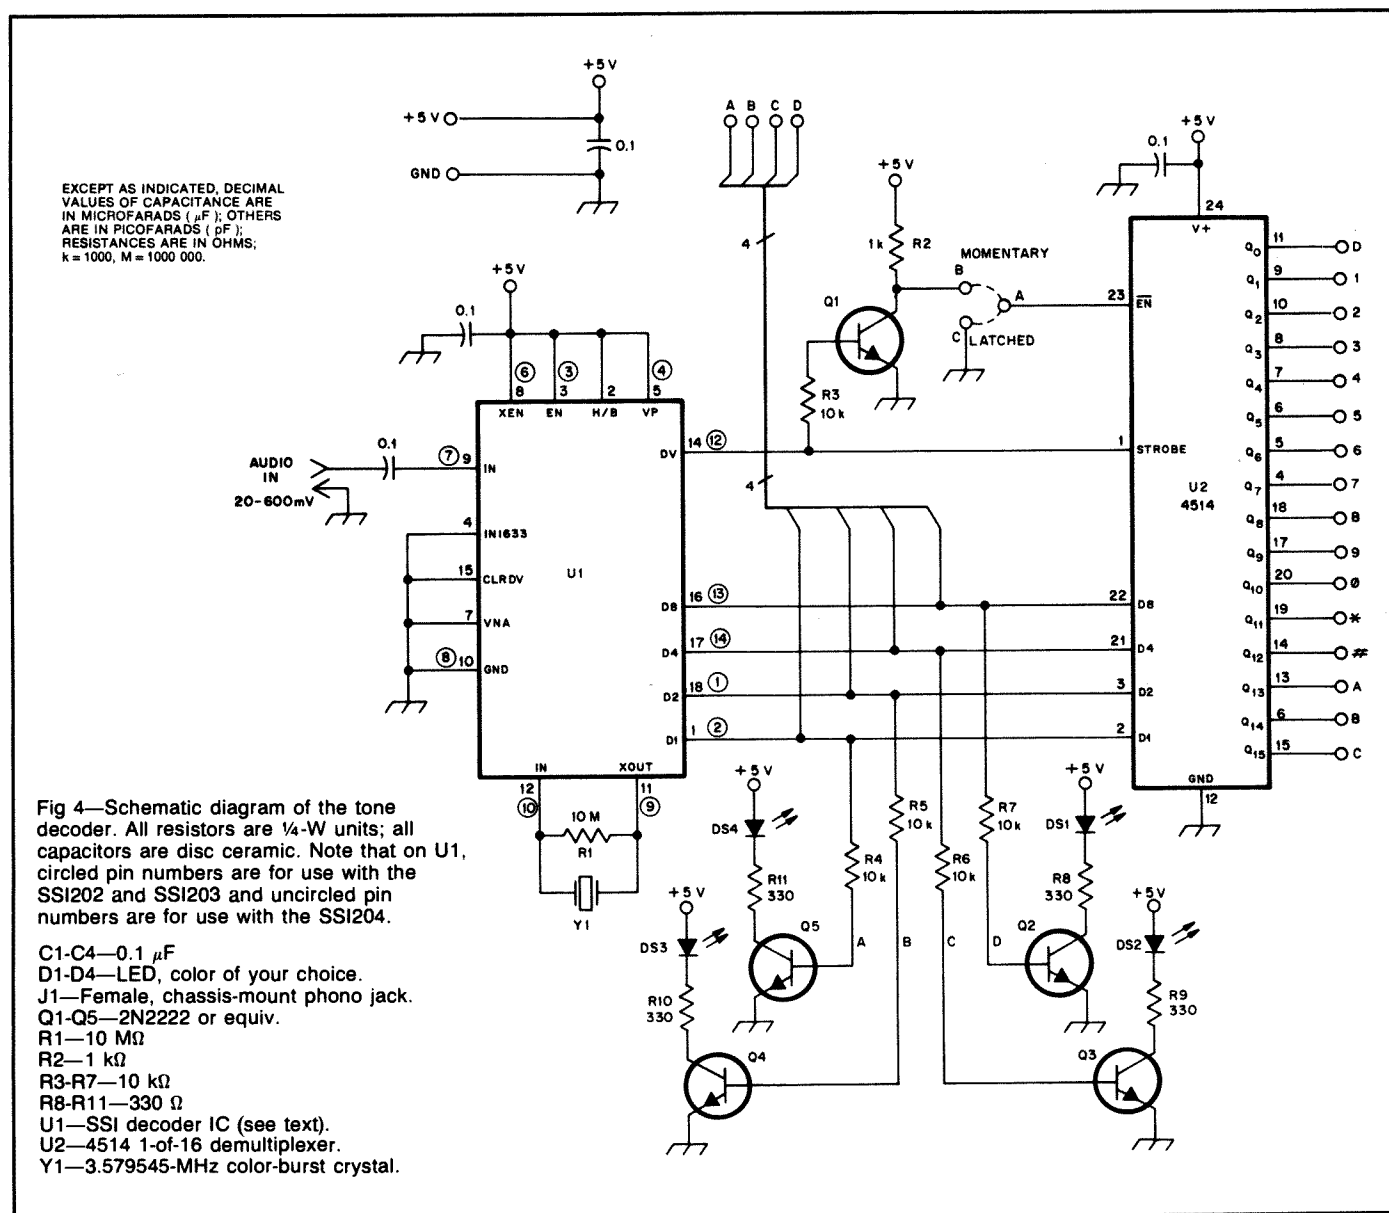

Fig 3—The simple DTMF decoder uses a minimum of parts and fits on a compact PC board.

opposed to other methods, and the finished unit is also considerably smaller.<sup>1</sup> The project shown in Figs. 3 through 8, designed and built by Tom Miller, KA1JQW, in the ARRL Lab, uses the SSI202, SSI203 or SSI204 as a one-of-sixteen tone decoder.

### Circuit Details

The decoder described here is designed so you can tailor the circuit to suit your needs. As mentioned before, three different SSI chips can be used. All produce the same results and are available from different sources at various prices. Fig. 4 shows the decoder schematic. Audio containing the DTMF tones is fed into the circuit at the AUD IN jack. The input amplitude should be between 20 and 600 mV RMS. The signal is ac-coupled and fed directly into the decoder IC. Notice that there are two sets of pin numbers for U1. The circled numbers are for use with the SSI204, and the uncircled numbers are for use with the SSI202 and '203.

Inside the decoder chip, the audio signal is filtered to rid it of noise and 60-Hz hum, and then split into two bands, one for high tones, and the other for low tones. From there, the two bands are further filtered and fed into the tone-detection circuits. The tone detection circuits compare the frequency of the incoming signal to that of an internal clock signal. This clock signal is generated by dividing down a crystal-controlled 3.579545 MHz oscillator (from a common color-burst crystal). Once detected, the outputs send the corresponding binary word and a strobe (called DV) for use by an external circuit.

The circuit described here uses a 4514 (1-of-16 decoder) to decode the binary output into 16 separate logic-level outputs. These outputs can be momentary (by installing a jumper between points A and B) or latched (by installing a jumper between points A and C). Some sort of driver circuitry must be used to prevent damage to the 4514. Examples of driver circuits are shown in Fig. 5.

The four data outputs from U1 are also available for use, and LEDs indicate activity. The strobe from the tone decoder is not specifically designated as an output on the circuit board. It can, however, be taken off the board from pin 1 of the 4514 or the collector of Q1 if the compliment is necessary. This will allow you to strobe the binary word onto a computer bus or other control device.

The circuit requires a single 5-V supply. It can readily run from 12-V dc or 117-V ac using the suggested power supply circuits

shown in Fig. 6. Maximum current consumption at 5 V is 60 mA with all four LEDs lit, and 20 mA with no LEDs lit.

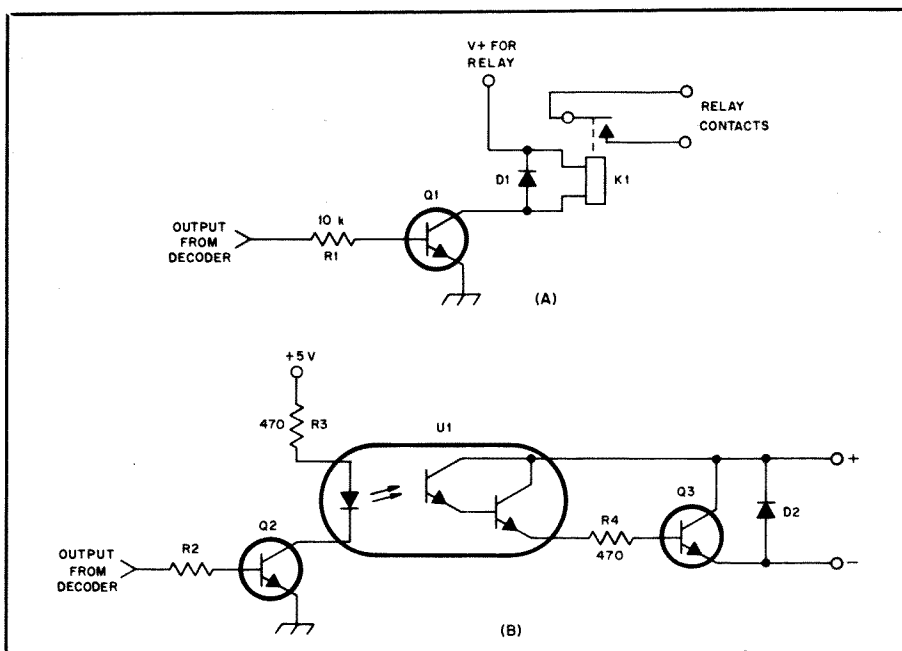

Fig. 5—Suggested driver circuits for use with logic level outputs. A typical relay or solenoid driver is shown at A, and B shows a typical high current/voltage driver with an opto-isolated output stage. Resistors are 1/4-W units.

### Construction

The PC-board etching pattern is located at the back of this book. Fig. 7 shows the component layout from the component side of the board. Use sockets for the ICs, as this makes testing and repair easier. The board was designed for use with any of the SSI chips, so care should be taken when stuffing the circuit board—it is very easy to place the U1 in the wrong set of holes. If you are using the 14-pin variety decoder (SSI204), it should be located in the set of holes nearest to the crystal with pin 1 in the square pad. Conversely, if you are using one of the 18-pin decoders (SSI202 and '203) for U1, use the set of holes farthest from the crystal. Once again, be sure that pin 1 is located correctly. Fig. 8 shows two of the finished units, one using the SSI202, and the other using the SSI204. Notice the slight difference in location of the ICs; the two sets of holes are offset just enough to allow you to use one set and not the other.

If the decoder is to be used in a high-RF environment, such as that of a repeater controller, some precautions should be taken to ensure that there is no interference to the decoder. In this case, the unit should be housed in a closed aluminum chassis. Use a shielded wire and connector for the audio line, and install plenty of bypass capacitors in the power supply.

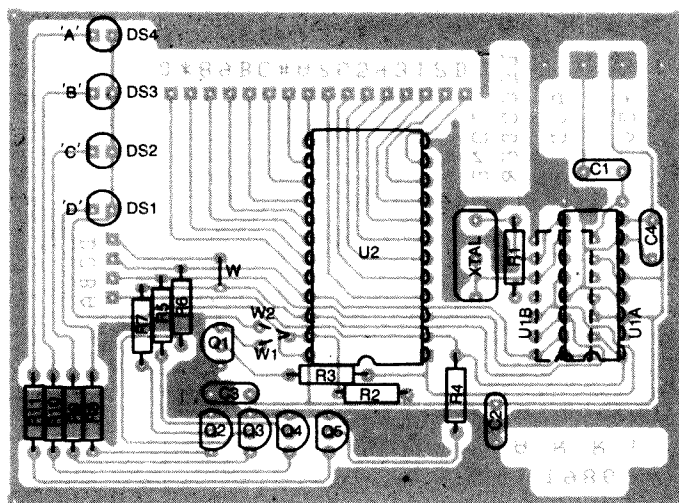

### Testing/Set Up

Once the unit has been built, remove the ICs and apply 5-V dc to the power supply connections on the PC board. Then check the power-supply pins on the IC sockets with a voltmeter to be sure that the power supply is working properly and is correctly polarized. Then turn off the power and install the ICs. Although these steps might seem trivial, they can save a lot of grief from burned-out ICs.

Be sure that the right jumper (not both) is installed between point A and point B or

C. Apply power once again. Next, you'll need a source of DTMF tones to test the unit. An easy source of the required tones is a pair of hand-held VHF transceivers. One must have a tone pad; this will be connected to a dummy load and used for transmitting the required tones. Connect the speaker output of the other hand-held transceiver to the decoder and set the audio output to low volume. Upon sending an audio tone pair to the decoder, the LEDs

should indicate the corresponding binary word for as long as the tone is present. Table 1 shows the correlation between tone pairs and which LEDs are lit. Note that the output of the decoder IC is standard binary. The LED indication is not latched when a jumper is installed between points A and C; just the 1-of-16 outputs are latched. The completed unit is now ready for installation in the device to be controlled.

W = Jumper

# A PIN-Diode TR Switch

The TR switch system described here is usable with almost any tube-final 100-W (output) power level transmitter/receiver or transceiver/receiver combination. This system is designed for flexible operation and interconnection to various pieces of commercial or homemade equipment. For the simplest setup, no modifications to the transmitter or receiver are necessary. All that's required is to plug the station equipment into the system.

The only limitation associated with this simple setup is the recovery speed of the receiver. If the receiver AGC time constant is fairly fast, it should be possible to hear signals between characters at keying speeds of up to 25 WPM. If the receiver AGC is turned off, or set for very fast recovery, signals can be heard between characters at speeds of up to 50 WPM. If you prefer, the receiver can be muted during characters. Two outputs, the + mute and - mute are provided for this purpose. Several transmitters were tried with this system, and it was possible to use them without modification, so long as the final amplifier was biased off under key-up conditions. No background hash was noticeable.

The PIN-diode TR system is not plagued by problems commonly associated with some other systems. First, "suckout" (receiver desensing) has been eliminated, as has the problem of critical interconnecting line lengths. Also, since the saturated-diode technique has been abandoned there should be no chance for TVI. No high-priced vacuum relays are used. No amplifiers are placed ahead of the receiver that could affect receiver performance. In short, the system described here provides excellent performance and suffers none of the ills of earlier designs.

## The Circuit

A schematic diagram of the circuit is shown in Fig. 15. The diagram is divided into two sections, as is the actual circuitry. That portion of the circuit to the left of the dotted line is intended to be mounted at the operating position for easy access. Circuitry to the right of the line can be mounted remotely, perhaps behind the station equipment.

The transmitter is connected to the antenna through a quarter-wavelength, lumped-constant circuit. S1 selects the appropriate circuit for the frequency in use. Quarter-wave circuits are required to prevent suckout of the received signal. Suckout occurs with tube-type transmitters when the high-impedance end of the transmitter pi network becomes unloaded; during receive periods, for example. As the pi network is one type of impedance-inverting network, the high resistance presented by the non-operational tube causes the low-impedance end of the network to approach 0 ohms. The quarter-

Fig. 14 — Exterior view of the PIN Diode TR Switch. The box at the right is mounted at the operating position. The box at the left can be mounted remotely.

wavelength lumped-constant sections provided in the TR system serve to step the nearly zero impedance level of the transmitter output up to an almost infinitely high impedance that will not reduce the received signal level. As shown in the schematic diagram, the antenna is connected directly to J3 which feeds the PIN-diode switch section of the TR circuit.

The components located between J4 and J5 comprise the switch that protects the receiver from the transmitted signal. A T configuration is used, with D1 and D2 connected in series and D3 in shunt. Combination switches provide better attenuation performance than either the series or shunt elements alone. Approximately 50 dB of isolation from the antenna to the receiver connection is provided throughout the RF range. These results should be reproducible if the same type of PIN diodes are used and the board layout shown is followed closely.

The station keyer (or straight key, bug or keyboard) is connected to either J6 or J7, depending on the output keying potential. Q1 and Q2 provide a suitable signal for driving Q3 through Q9. Q3 controls D3 and turns the diode on during transmission and off during receive. Q4 and Q5 control D1 and D2, biasing the diodes on for receive and off for transmit. At first glance it might appear that some simplification of the switching diode and control circuitry might be possible. Because it was desired to power the system from a 12-V dc source (for portable operation), and high negative voltages could not be used to reverse bias the diodes during transmit, an unusual arrangement was devised. Hence, the more complicated circuit. J8 and J9 are provided for keying the transmitter; one of the two outputs should be suitable for almost any transmitter. J10 and J11 are for muting the station receiver during transmission. Again, dual-polarity outputs are provided. Choose the one applicable to the equipment in use.

The power supply is depicted at the bottom center of the schematic diagram. Power to the system is routed through an

ON/OFF switch that is mounted at the control head. An LED indicator is included as a reminder that power is switched on. Connection from the control head to the remote unit is made via feedthrough capacitors at each box. These capacitors ensure that each cabinet remains RF-tight. A step-down transformer, full-wave rectifier, filter and three-terminal regulator provide the necessary voltage. A fuse is included in one leg of the ac line.

## Construction

As mentioned earlier, the TR switch system is constructed in two enclosures. The circuitry intended for mounting at the operating position is built into a Bud Minibox that measures 3 × 4 × 5 inches. The part number of this box is CU-3005A. This enclosure houses the circuit-board mounted quarter-wavelength sections, rotary switch, ON/OFF power switch, LED indicator, coaxial connectors and feedthrough capacitors. An interior view of this unit is shown in Fig. 16. The rotary-switch wafers are positioned to line up closely with the appropriate circuit board connection points. An extra ceramic spacer is inserted in each of the switch section support rods to provide the needed separation. Short lengths of no. 18 tinned wire are used for the connections from the board to the switch contacts. RG-58A/U cable is used to make the connection from the antenna coaxial connector to the front wafer. The cable braid is soldered to ground lugs at each end.

The second enclosure used for the TR switch system is constructed from sheet aluminum and measures 2-1/8 × 4-1/8 × 7 inches. An ideal commercial enclosure would be the Bud CU-247 die-cast aluminum box. These boxes are extremely rugged and RF tight. The power supply, PIN-diode switch and control circuitry are mounted on a circuit board. Circuit-board parts-layout information is shown in Fig. 18. Double-sided circuit-board material was used, with the top side of the board left substantially unetched to act as

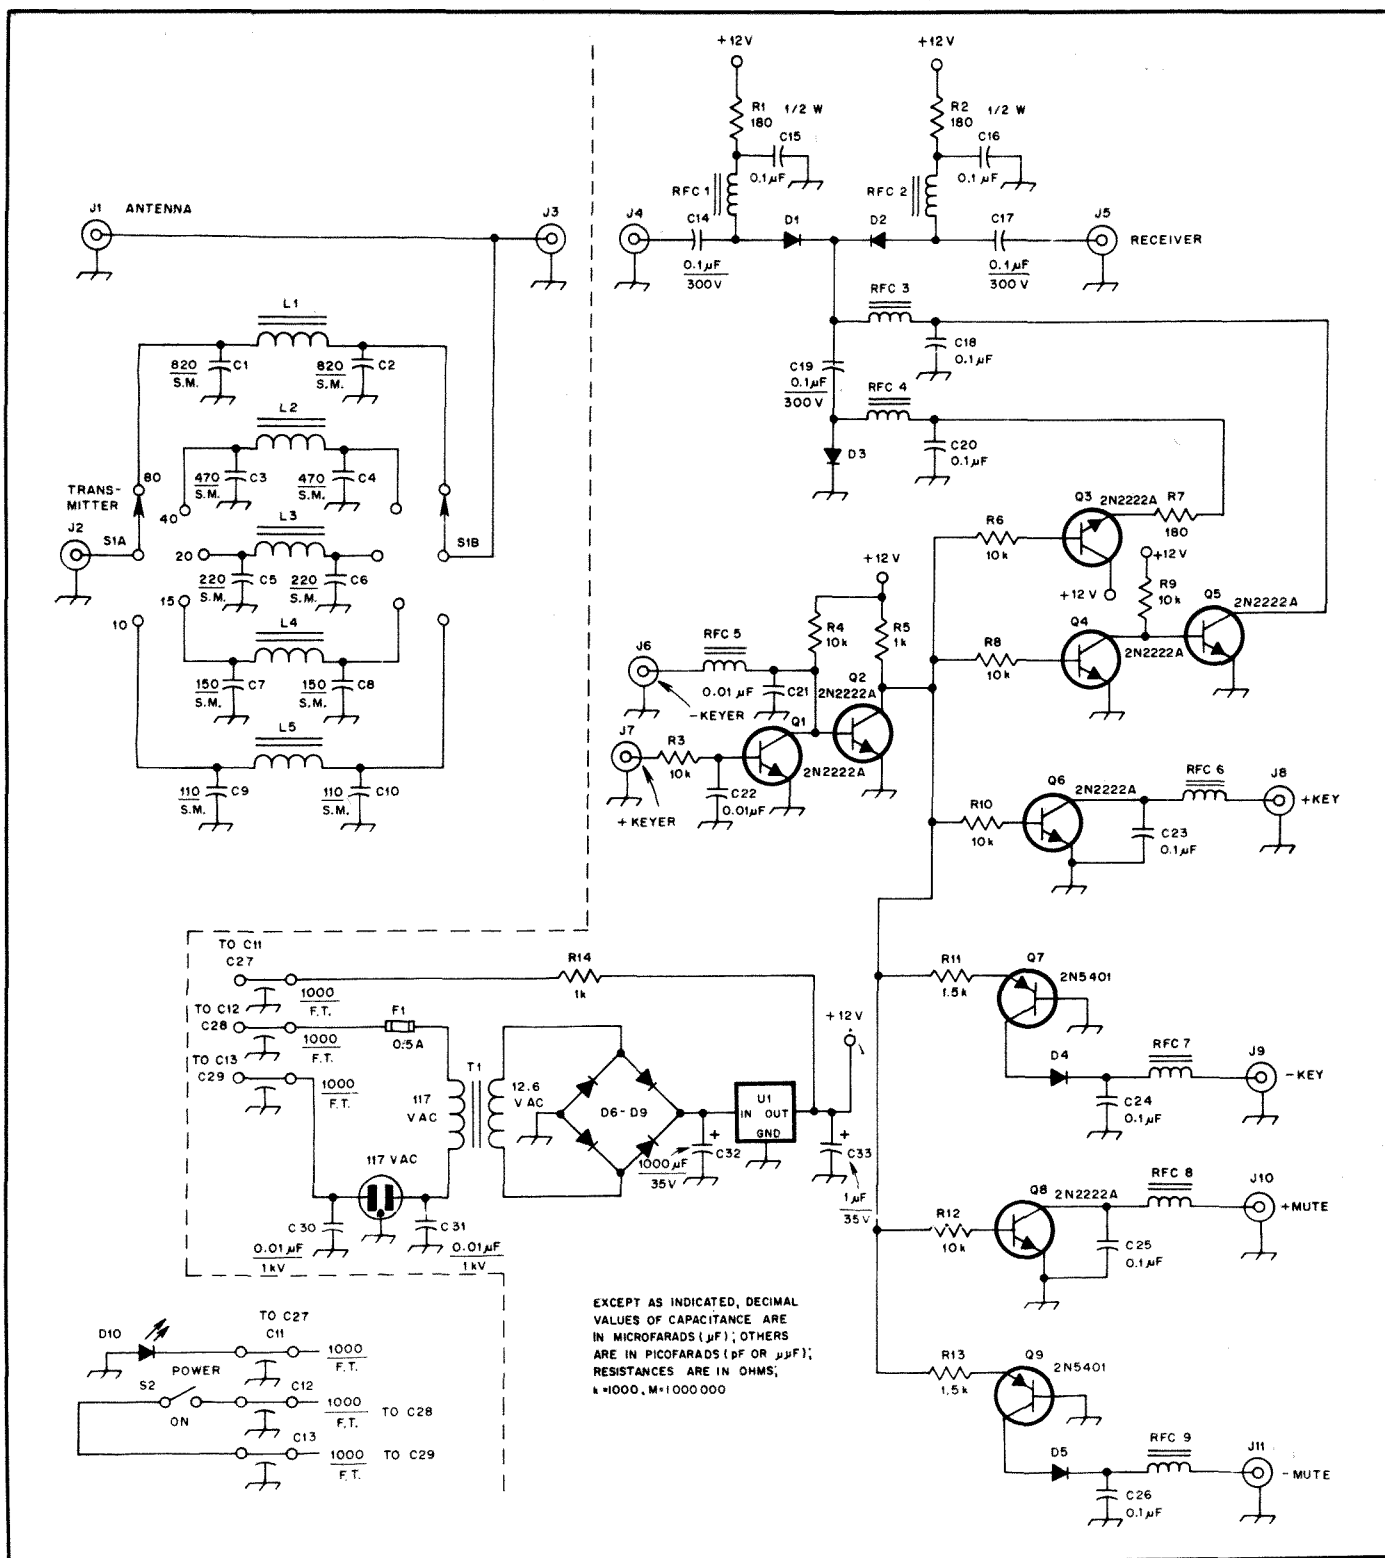

Fig. 15 — Schematic diagram of the TR system. All resistors are  $\frac{1}{4}$ -watt composition types. All capacitors are miniature ceramic, 50-volt types unless polarity is indicated. Polarized types are aluminum electrolytic or tantalum. Component designations listed in the schematic, but not called out in the parts list, are for text or layout reference only.

Fig. 16 — Interior view of the control head. The quarter-wave sections are mounted to the single-sided PC board.

a ground plane. Copper must be removed from around circuit-hole locations for components that are not connected to ground. This can be accomplished in the etching process with the aid of the top-side etching pattern. Alternatively, the copper can be removed from around holes with a large drill. Do not remove copper from around holes where component leads are grounded. Many of the component ground connections are not made on the pattern (bottom) side of the board. These components must be soldered on the top side to complete the ground connection.

Garden-variety components are used, with the exception of the PIN diodes. The diodes are Unitrode 1N5767 types, which can be obtained from many supply houses. Microwave Associates makes several suitable replacements. All of the RF chokes are hand wound on small ferrite cores. Since encapsulated chokes are relatively expensive and cores are not, the time spent winding the chokes can result in reduced cost.

### Circuit Checkout

Interconnection of the two modules requires four lengths of hookup wire, each long enough to reach between the two units when installed in their operating positions. The wires are twisted, cable-tied or laced together. Wires of different colors will help distinguish the connections and prevent possible surprises the first time power is applied! Connections are as follows: C11 to C27, C12 to C28 and C13 to C29. The fourth wire, ground, connects the two boxes. A coaxial cable is used to connect J3 and J4.

Connection to the station equipment is a simple matter. The keyer is plugged into either J6 or J7. If the keyer provides a positive voltage when keyed, use J7. If the keyer provides a ground, use J6. Connect

Fig. 17 — Inside view of the remotely mounted portion of the system. Short lengths of wire are used to attach the connectors to the appropriate circuit-board foils. All power supply components are mounted on the circuit board.

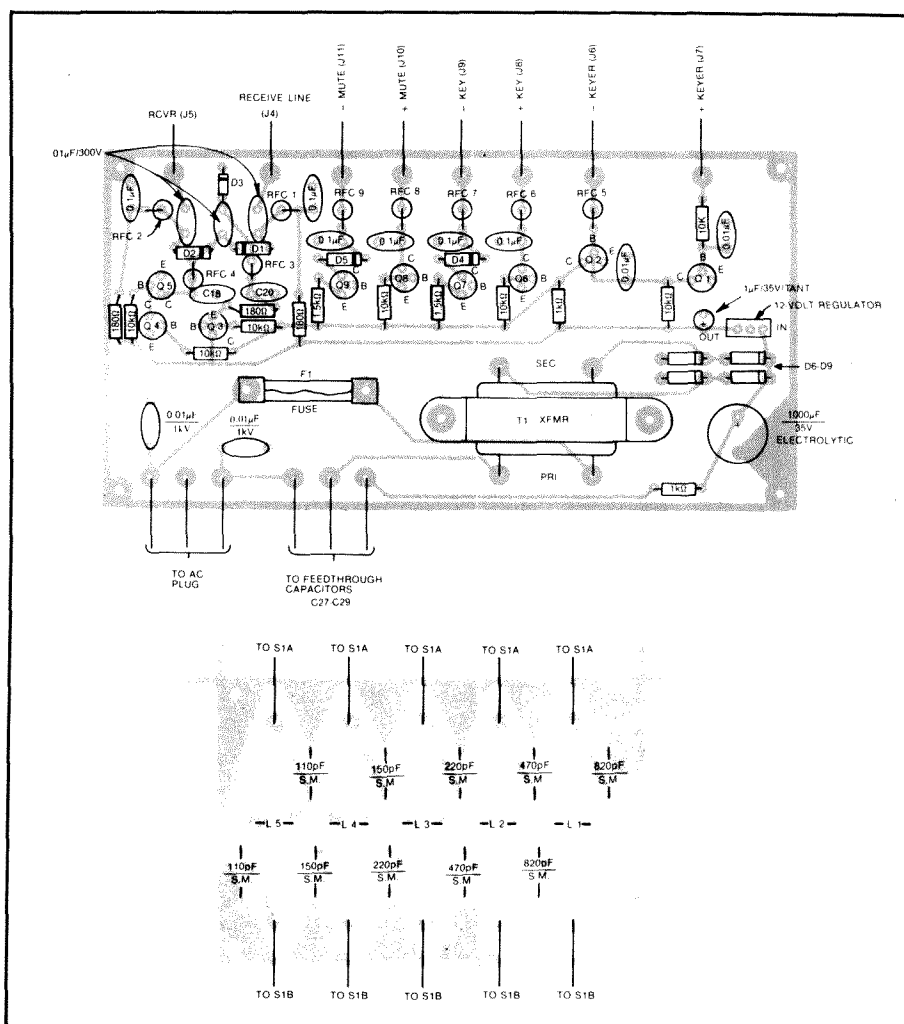

Fig. 18 — Parts-layout patterns of the two printed-circuit boards. Each board is shown from the component side with an X-ray view of the foil. Full-size etching patterns can be found at the back of this book.

the antenna to J1 and the station receiver to J5. Do not connect the transmitter at this time. A check of the system operation can now be made. If all is in order at this point, signals should be heard in the receiver. Actuating the keyer should cause the signals to become inaudible.

The exact amount of attenuation can be measured using a calibrated signal generator or a step attenuator and received signals. Attenuation should be on the order of 50 dB. If no measurement equipment is available, a received signal and the receiver S meter may be used. A strong signal

should become almost completely buried in the receiver noise when the keyer is activated. Connect the transmitter output to J2 and install a cable between the transmitter key jack and J8 or J9. If muting of the receiver is desired, make the appropriate connection at J10 or J11.

## QRP SWR Indicator

This compact SWR indicator is suitable for use with transmitters in the 1- to 150-watt output range. It will function properly from 1.8 to 30 MHz. The project, shown in Fig. 19, was first described by Doug DeMaw, W1FB in the Hints and Kinks column of August 1982 *QST*.

The principal difference in this circuit from some others is that a two-turn link is wound on T1 to increase the low-power sensitivity of the instrument. Normally, a single wire is passed through the center hole of the toroidal transformer for sampling the 50-ohm transmission line. See Fig. 20.

Most of the components were garnered

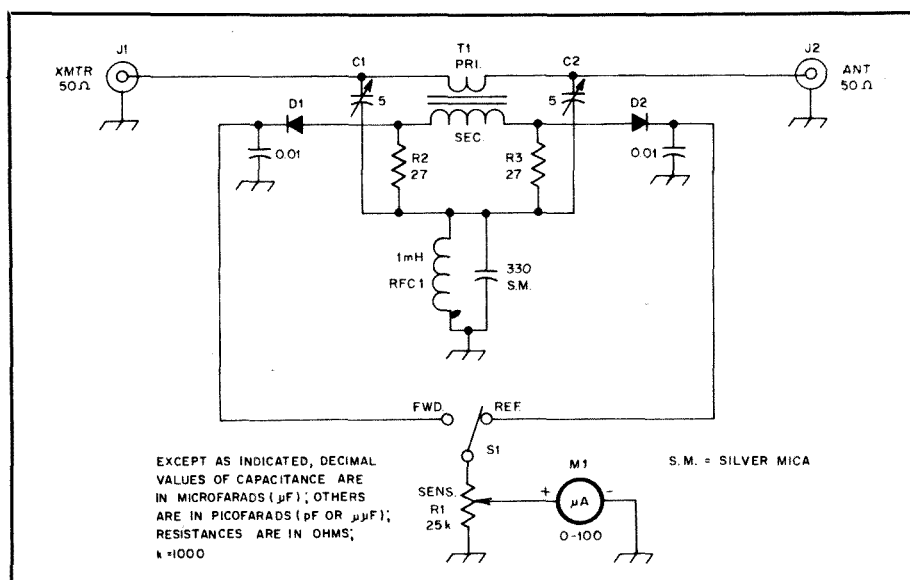

Fig. 20 — Schematic diagram of the SWR indicator. Fixed-value capacitors are disc ceramic except those marked with SM, which are silver mica. R2 and R3 are 1/4-watt carbon-composition units.

C1, C2 — Miniature PC-mount air trimmer (see text).

D1, D2 — Silicon switching diode. 1N914 type, matched for equivalent forward resistance (use an ohmmeter).

J1, J2 — Single-hole-mount phono jack.

M1 — Miniature 50- to 100- $\mu$ A dc meter (see text).

R1 — Linear-taper miniature control, 25 K $\Omega$ . RFC1 — Miniature 1-mH RF choke.

S1 — Miniature SPDT slide or toggle switch.

T1 — Toroidal transformer. Secondary: 60 turns no. 30 enam. wire on an Amidon, Radiokt or Palomar T68-2 powdered-iron core. Primary is two turns over secondary winding.

at hamfest flea markets. A miniature FM tuning meter is used at M1. It has a 100- $\mu$ A movement, but microampere meters of other full-scale characteristics will work nicely in this circuit. A miniature slide switch is used for S1, while nulling trimmers C1 and C2 are surplus PC-mount

trimmers. Piston trimmers can be used in place of the units shown for C1 and C2. The type chosen should be mechanically stable and capable of withstanding at least 87 volts RMS (typical maximum voltage for 150 watts at 50 ohms). Greater voltages may be present in a mismatched system.

Fig. 19 — Photograph of the assembled SWR indicator in the homemade PC-board material box. A commercial cabinet or a Minibox can be used to obtain a more professional effect.

Use care in choosing the capacitors, with special attention to the minimum capacitance available. Only 2 or 3 pF of capacitance should be needed when the bridge is nulled for 50-ohm use.

Double-sided PC-board material is used for the case. It is soldered together along the inner seam of the walls and the base plate. The top plate is tacked to the case, using one solder blob on each side. This should be done after the circuit has been adjusted and is considered ready to use.

The PC board is supported in the box by means of a single standoff post, directly under T1. The rear edge of the PC board butts firmly against the back wall, as shown in the photograph. Be sure to connect the ground foil of the PC board to the box walls. Two short lengths of bus wire can

be used for the purpose. A glob of noncorrosive RTV sealant is placed in the center hole of T1 to keep the transformer in position. Similarly, M1 is glued to the front panel by means of quick-drying contact cement. Four adhesive-backed plastic feet are attached to the bottom plate of the instrument. You can use label tape to identify the controls and the input/output jacks on the rear of the box.

Adjustment is done by connecting a 50-ohm resistive termination to the antenna jack, applying RF energy to the transmitter jack and adjusting R1 for a full-scale reading (S1 in the FWD position). Next, switch S1 to REF and adjust the trimmer that causes the meter reading to change (one of the trimmers will be unresponsive

in this setting). Set the trimmer for minimum meter deflection. It should read zero. Next, reverse the cables at J1 and J2. Put S1 in the REF position and apply RF energy. The meter should read full scale. Switch S1 to FWD and adjust the remaining trimmer for minimum meter reading (again, it should fall to zero). The bridge has now been balanced for 50 ohms. This set of adjustments should be done on 20 or 15 meters to ensure proper high-range performance.

When using the instrument, always adjust R1 for a full-scale reading with S1 in FWD mode. Adjust the antenna or antenna-matching network for the lowest reading attainable with S1 in the REF position. A zero reading in REF will be equivalent to an SWR of 1:1.

## Digital PEP Wattmeter and SWR Calculator

Every radio amateur wants to measure transmitter power or transmission-line SWR at some time. The wattmeter and SWR calculator shown in Figs. 21 through 31 will allow the operator to perform these simple operations for peak-envelope power (PEP) in forward and reverse directions and automatically calculate SWR with no adjustments once the unit is calibrated. The unit reads from 0 to 2000 watts and SWR from 1.00 to 19.99. Because it measures PEP, the unit satisfies FCC requirements for monitoring your power output. The RF sampling unit is designed to operate from 160 through 6 meters. This project was designed and built by Jon Towle, WB1DNL, in the ARRL lab.

### Circuit Description

The wattmeter and SWR calculator consists of four parts: An RF current sampling unit, a peak measuring and calculator board, an LCD digital display with  $3\frac{1}{2}$

digit A/D converter and a four-voltage power supply.

The RF sampling unit circuit is shown in Fig. 22. It consists of a wideband current transformer (T1) and a capacitive voltage divider. The circuit produces a voltage that is proportional to the power in the transmission line at each of the feed-through capacitors. These are high impedance outputs, and are connected to the op-amp inputs on the calculator board.

The primary of T1 is simply a short section of RG-8 coaxial cable soldered between the input and output connectors. The secondary is a ferrite toroid core with the appropriate number of turns. Thirty turns on the core provide 10-V output from the current transformer when operated at the 2000-W level. A 10-turn secondary would provide 10 V at the 200-W level if more accuracy is desired at low power levels. The toroid slips over the center of the outer jacket of the section of RG-8. The 1N34A diodes, 22-ohm resistors and 3-pF capacitors should be matched for best performance.

The sampling unit in the wattmeter shown here is attached to the back of the cabinet. The forward and reflected voltages from the sampling unit can also be fed to the main unit through shielded cable (such as RG-174) if you want a remote-sensing wattmeter. In this way, the sensing unit can be connected directly at the transmitter output (or directly to the antenna terminals).

The calculator board (Fig. 23) performs several functions. First, two peak detector circuits (U1) look at the maximum voltage from the RF sampling unit. A one-second time constant holds the peak voltage sufficiently long to view the power output on the display. The peak detector circuit uses a TL084 quad op-amp, which has a very

- C3, C4 — 37- to 250-pF mica compression trimmer capacitor (Arco 426 or equiv., avail. from RadioKit).
- J1, J2 — SO-239 coaxial connector.
- RFC1, RFC2 — 4t no. 24 enam. on 3/8-inch-OD, 850- $\mu$ i ferrite bead (Amidon FB-43-2401 or equiv.).
- T1 — Wideband current transformer. Primary, section of RG-8 through center of core; secondary, 30t no. 22 enam. on Amidon FT-82-61 toroid core (125  $\mu$ i). See text and Fig. 26.

high input impedance, to avoid loading the output from the RF sampling unit.

A TL082 dual op-amp (U2) is used for two functions. U2A is wired as a summing amplifier, while U2B is connected as a difference amplifier. The output of the peak detector circuits is applied to both U2A and U2B to give sum and difference voltages. That is:  $V_F + V_R$  and  $V_F - V_R$ . These values are used to calculate SWR.

Fig. 21 — Front-panel view of the digital PEP wattmeter. The LCD display is mounted directly to the front panel.

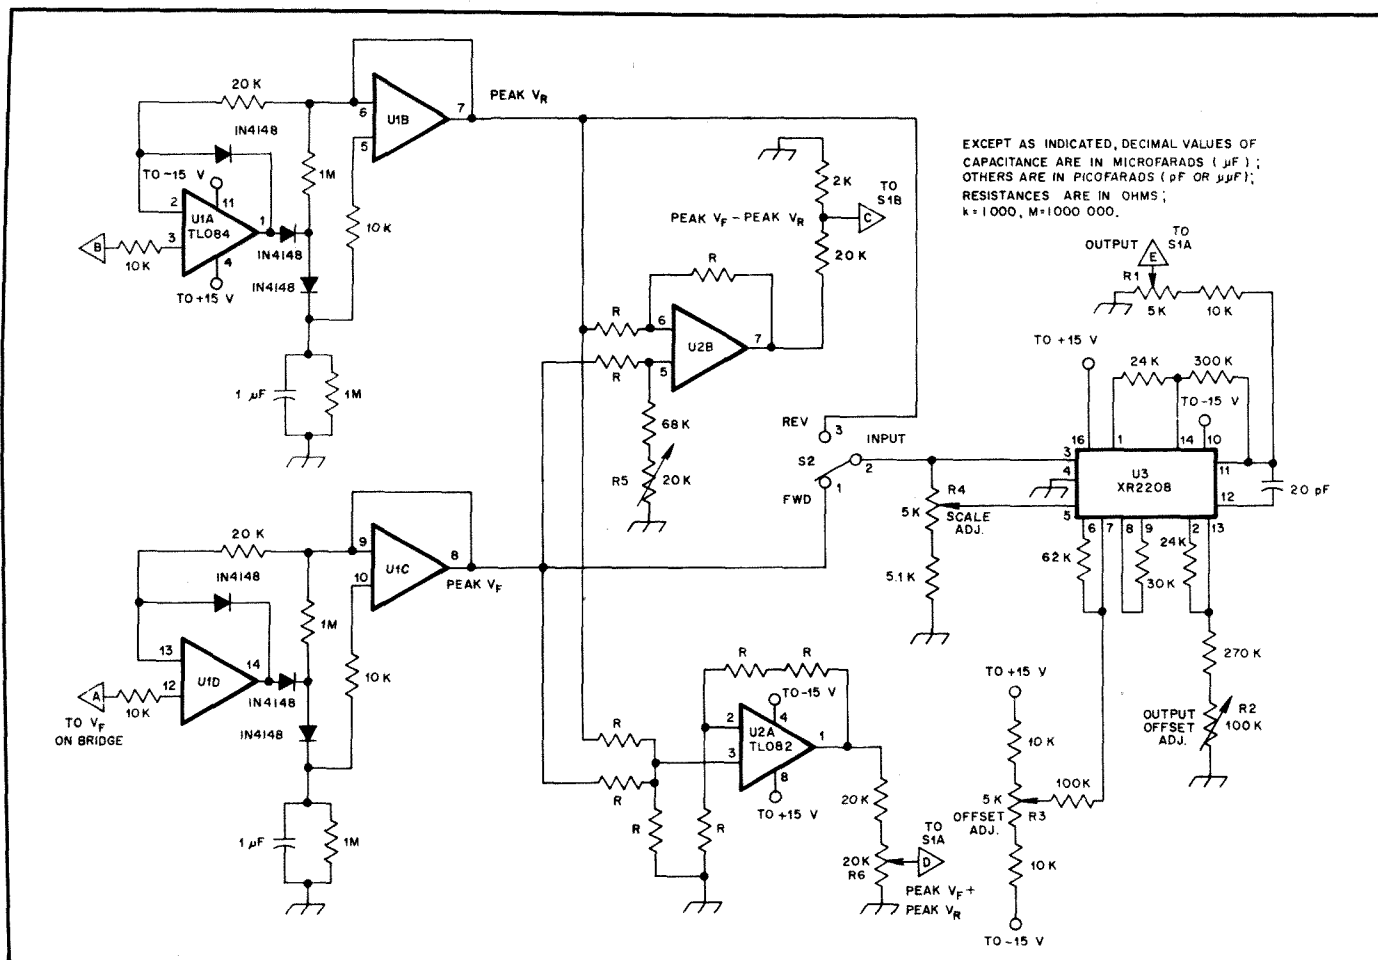

Fig. 23 — Schematic diagram of the calculator board. All resistors are 1/4-W, 5% types unless otherwise noted. Capacitors are disc ceramic.  
R — 82.5-kΩ, 1/4 W, 1%, 50-ppm metal-film resistors. See text.  
R1-R6 — Multiturn Cermet trimmers (Bourns BP3299W series or equiv.).  
U1 — TL084 BIFET quad operational amplifier.  
U2 — TL082 BIFET dual operational amplifier.  
U3 — Exar XR2208 operational multiplier (Avail. from Jameco Electronics, 1355 Shoreway Rd., Belmont, CA 94002).

An Exar XR-2208 operational multiplier IC, U3, is wired as a squaring circuit to make the conversion to watts for the digital display. The output of either peak detector circuit can be applied to the input of the multiplier through S2. This output is scaled by R1 and is proportional to the output power in watts.

The LCD display is controlled by an Intersil ICL7106 3 1/2 digit single-chip A/D converter. Fig. 24 is a schematic diagram of this circuit, which is wired as a 0- to 2-volt voltmeter for this application. No decimal point is used in the wattmeter mode, so the range is 0 to 2000 watts. Also, no provision is made to change scales between high and low power. This is because the full-scale range is determined by the RF sampling unit. A multi-turn potentiometer, R7, is used to set the 1.000-V reference for the ICL7106.

The ICL7106 A/D converter operates by calculating the ratio between IN HI and REF HI (pins 31 and 36). This makes it easy to compute SWR, which is the ratio of the maximum voltage to the minimum voltage in the transmission line. In the SWR mode, the difference voltage from the calculator board is applied to

REF HI, and the summed voltage is applied to IN HI. To get a useful range of SWR, R6 on the calculator board is used to scale IN HI for a range of 1.00 to 19.99. The decimal point indicates only in the SWR mode.

The power supply uses common three-terminal regulators to generate the ±15-volt supplies for the op-amps and the multipliers and the ±5-volt supplies for the A/D converter. T1 has a dual 17-V ac secondary; it is connected to give separate full-wave, center-tapped outputs for the negative and positive supplies. A complete schematic diagram is given in Fig. 25.

#### Construction Details

The RF sampling unit is built in a Hammond 1590B die-cast box for maximum shielding. Fig. 26 shows how the parts are arranged inside the box. The components are mounted on a PC board (Fig. 27). Surface-mounting techniques are used to make the RF sampling unit small and simple. Don't forget to solder a wire from the shield of the T1 primary to ground!

Two SO-239 connectors are attached to the outside of the box cover. The mounting screws for the connectors are also used

to secure the circuit board to the inside of the cover. Mounting the connectors on the outside allows plenty of room inside for T1. Holes drilled in the bottom of the die-cast box allow access to C3 and C4 for nulling the bridge. Only one end of RFC1 and RFC2 is soldered to the circuit board. The other end of each RFC solders to one side of a feedthrough capacitor. The feedthrough capacitors mount in holes drilled in the bottom of the box.

Assembly of the calculator board shown in Fig. 28 is very simple. The resistors marked R on the schematic must be 1% resistors. The actual value used may be anywhere in the range of 75 kΩ to 100 kΩ, but all resistors used at these points must be within 1% of each other. You will see the best possible performance if you measure the values of the resistors before using them and discard those that are not within 1% of the desired value. It pays to order a few extra so they can be matched during construction. The 82.5-kΩ units used in the unit shown here are available from Mouser Electronics, Digi-Key and other sources listed in Chapter 35. The 1N34A diodes may be available from Radio Shack.

Fig. 24 — Schematic diagram of the digital display and A/D converter. Resistors are  $\frac{1}{4}$ -W, 5% types unless otherwise noted. Capacitors are disc ceramic.

R7 — Multi-turn 10-k $\Omega$  potentiometer.  
U4 — Intersil ICL7106  $3\frac{1}{2}$ -digit, single-chip A/D converter (Avail. from Jameco

Electronics).  
U5 — FEO203D  $3\frac{1}{2}$ -digit LCD display for ICL7106 (Avail. from Jameco Electronics).

The circuit board layout seems to be critical around U3, so changing the artwork provided may result in drifting or unstable performance. Other than this one area, layout is not critical.

The ICL7106 A/D converter and the LCD digital display are mounted on one circuit board. Layout is shown in Fig. 29.

The ICL7106 is a CMOS device and should be handled with care. The LCD display is sandwiched between thin glass plates and should also be handled carefully. Static charge may cause segments to illuminate when handled. This is not a problem. Do not apply dc to the display because this may damage the segments. The board is laid out

to accommodate low-profile sockets for both ICs. The display socket is made from a normal 40-pin socket that is cut in half lengthwise.

Power supply components, including T1, mount on a PC board. Layout for this board is given in Fig. 30. Layout is not critical; the power-supply board was made exactly the same size as the calculator board for ease of mounting, as detailed below. Heat sinks are necessary on the 15-V regulators. Remember that the tab of U2 is connected to the input, while the tab of U1 is connected to ground. Do not allow the U2 heat sink to contact the U1 heat sink, the chassis or any other components! If possible, mount U2 to its heat sink with insulating hardware.

This project has been designed to fit inside a Hammond 1426K-B equipment box. Fig. 31 shows the inside of the finished unit. It is best to complete adjustments (outlined below) before mounting the wattmeter in the enclosure. The display board mounts behind the front panel. The calculator board and power supply are stackable and mount to the cabinet bottom plate. Mount the calculator board on the bottom, upside down to allow access to the board adjustments through holes drilled in the bottom panel. The RF sampling unit attaches to the rear panel.

### Setup Procedures

**RF Sampling Unit** — Connect a 100-W transmitter to the input and a 50- $\Omega$  dummy load to the output of the sampling unit. Connect a high-impedance voltmeter to the VR output feedthrough capacitor (the reverse side of the bridge). Apply 100 W to the sampling unit and adjust C3 until you observe a voltage null on the meter attached to the VR feedthrough capacitor. Next, reverse the RF connections, connect the voltmeter to the VF feedthrough capacitor and adjust C4 until you see a voltage null on the forward side of the bridge also.

**Calculator Board** — Connect the inputs of the two peak detectors together (points A and B on Fig. 23) and apply 5.0-V dc. Adjust R5 so that the output of the difference amplifier (point C on Fig. 23) is 0.0 V. The output of the summing amplifier at pin 1 of U2 should be 10.0 V.

The squaring circuit requires several iterations for proper adjustment, but it is easy just the same. Connect a voltmeter to pin 11 of U3 (the output). Apply 0 V to the input (at S2) and set the output offset adjustment (R2) to indicate 0 V at pin 11. Next, alternately apply  $\pm 10$  V to the input and set the offset adjustment (R3) so the output value at pin 11 is the same for the positive and negative voltages. This may require several tries. Finally, with 10 V applied to the input, set the scale adjustment (R4) so the output voltage at pin 11 of U3 is 10 V.

**Display Board** — Apply voltage to the display board. Connect a voltmeter to U4, pin 36 and adjust R7 until the voltage at

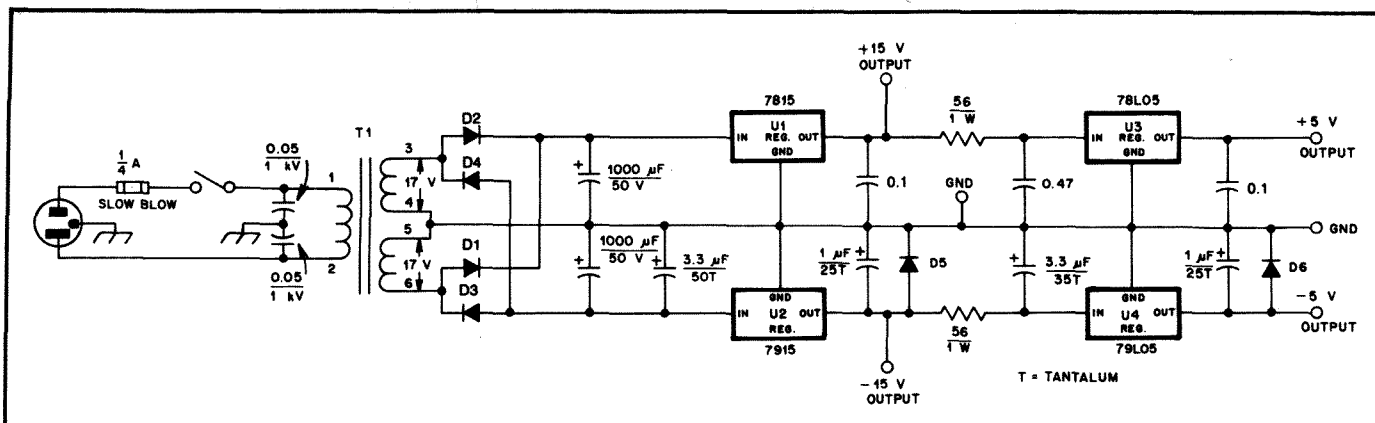

Fig. 25 — Schematic diagram of the PEP wattmeter power supply. Capacitors are disc ceramic unless otherwise noted. Capacitors marked with polarity are electrolytic.

D1-D6 — 100-PIV, 1-A diode (1N4002 or equiv.).  
T1 — Dual-secondary, PC-board mount transformer. Primary, 117-V ac; secondary, 17-V ac, 600 mA (Digi-Key T116-ND or equiv.).

U1 — 15-V, 1.5-A three-terminal regulator (LM7815 or equiv.).  
U2 — Negative 15-V, 1.5-A three-terminal regulator (LM7915 or equiv.).

U3 — 5-V, 100-mA three-terminal regulator (LM78L05 or equiv.).  
U4 — Negative 5-V, 100-mA three-terminal regulator (LM79L05 or equiv.).

Fig. 29 — Parts placement guide for the display board. A full-size etching pattern appears at the back of this book.

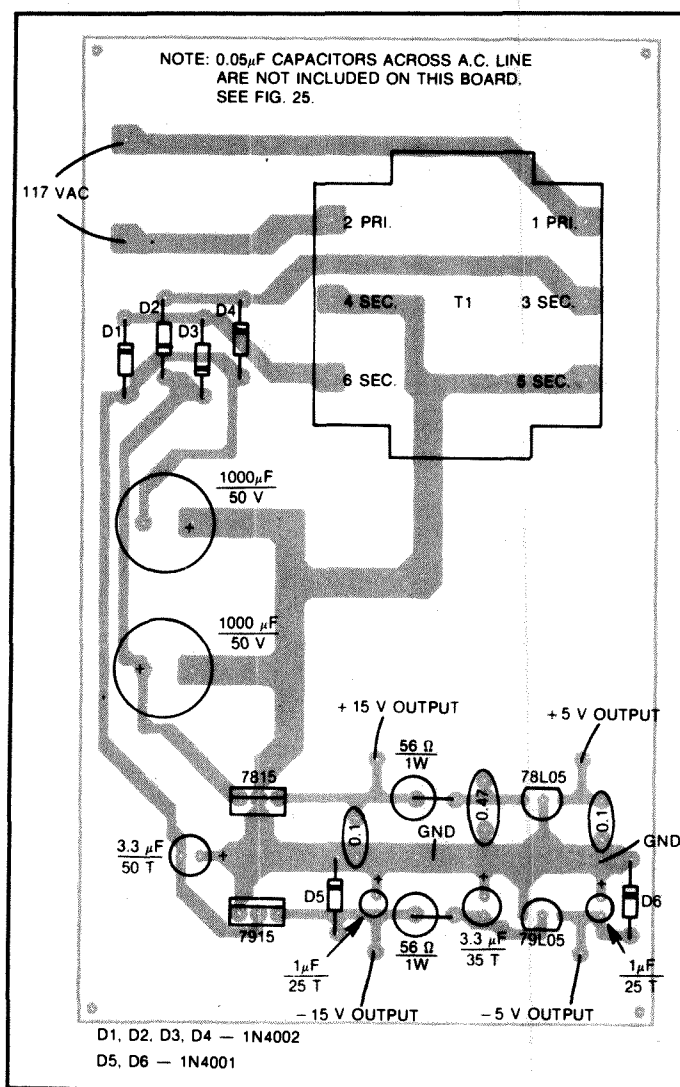

Fig. 30 — Parts placement guide for the power-supply board. A full-size etching pattern appears at the back of this book.

Fig. 31 — The power-supply and calculator boards are stacked on the bottom panel of the enclosure. The calculator board is not visible in this photograph. The RF sampling unit attaches to the rear panel, while the display board is attached to the front panel with standoff hardware. S1 and S2 also mount to the front panel.

pin 36 measures exactly 1.000 V. This sets the reference for U4.

**Final Calibration** — Connect the digital PEP wattmeter and a wattmeter of known accuracy in series between a transmitter and a good 50- $\Omega$  load. Apply power and adjust R1 until the PEP wattmeter reads the same power as the known wattmeter.

Disconnect VR from the input of the peak detector at point B and short the input to ground. Next, switch to the SWR mode and with RF applied, set R6 to read an SWR of 1.00. Reconnect VR to the peak detector and fully assemble the wattmeter/SWR calculator. Alternatively, the SWR reading can be adjusted by applying +5 V (from the power supply) to the  $V_F$  input (point A of Figs. 23 and 28) with the  $V_R$  input (point B) grounded. Set R6 to read an SWR of 1.00.

### Operation

The wattmeter operation is controlled by S1 and S2, which are mounted on the front panel. S2 allows the operator to view either forward or reflected power. S1 selects the power or SWR mode. In the SWR position, the display will flash random values because the A/D converter lacks a reference when there is no RF in the transmission line. This is normal and serves as a visual reminder that the SWR mode is in use.

## A Transmatch for Balanced or Unbalanced Lines

Most modern transmitters are designed to operate into loads of approximately 50 ohms. Solid-state transmitters produce progressively lower output power as the SWR on the transmission line increases, owing to the built-in SWR protection circuits. Therefore, it is useful to employ a matching network between the transmitter and the antenna feeder when antennas with complex impedances are used.

One example of this need can be seen in the case of an 80-meter, coax-fed dipole antenna which has been cut for resonance at, say, 3.6 MHz. If this antenna were used in the 75-meter phone band, the SWR would be fairly high. A Transmatch could be used to give the transmitter a 50-ohm load, even though a significant mismatch was present at the antenna feed point.

It is important to remember that the Transmatch will not correct the actual SWR condition; it only conceals it as far as the transmitter is concerned. A Transmatch is useful also when using a single-wire antenna for multiband use. By means of a balun at the Transmatch output it is possible to operate the transmitter into a

dipole, V beam or rhombic antenna.

A secondary benefit can be realized from Transmatches of certain varieties: The matching network can, if it has a band-pass response, attenuate harmonics from the transmitter. The amount of attenuation is dependent upon the loaded Q ( $Q_L$ ) of the network after the impedance has been matched. The higher the  $Q_L$ , the greater the attenuation. Some Transmatches, such as the Ultimate Transmatch of Fig. 33, can exhibit a high-pass response (undesirable), depending on the transformation ratio they are adjusted to accommodate. In a worst-case condition the attenuation of harmonic currents may be as low as 3 to 6 dB. Under different (better) conditions of impedance transformation, the attenuation can be as great as 20 to 25 dB.

The SPC Transmatch described here was developed to correct for the sometimes poor harmonic attenuation of the network in the Ultimate Transmatch. The SPC (series-parallel capacitance) circuit maintains a bandpass response under load conditions of less than 25 ohms to more than 1000 ohms (from a 50-ohm transmitter).

Fig. 32 — Exterior view of the SPC Transmatch. Radio Shack vernier drives are used for adjusting the tuning capacitors. A James Millen turns-counter drive is coupled to the rotary inductor. Green paint and green Dymo tape labels are used for panel decor. The cover is plain aluminum with a lightly grooved finish (sandpapered) that has been coated with clear lacquer. An aluminum foot holds the Transmatch at an easy access angle.

balanced transmission line, such as a 300- or 600-ohm feed system of the type that would be used with a multiband tuned

Fig. 33 — Circuit for the Ultimate Transmatch showing the network which can degenerate to a high-pass network under some conditions of transformation (see text). A T-network configuration will provide identical matching range, making a split-stator capacitor unnecessary at C1.

This is because a substantial amount of capacitance is always in parallel with the rotary inductor (C2B and L1 of Fig. 34). In comparison with the Ultimate circuit of Fig. 33, it can be seen that at high load impedances, the Ultimate Transmatch will have minimal effective output capacitance in shunt with the inductor, giving rise to a high-pass response.

Another advantage of the SPC Transmatch is its greater frequency range with the same component values used in the Ultimate Transmatch. The circuit of Fig. 34 operates from 1.8 to 30 MHz with the values shown. Only three-fourths of the available inductance of L1 is needed on 160 meters.

The notable difference in outward performance over the circuit in Fig. 33 is somewhat sharper tuning. This is because of the increased network Q. This is especially prominent at 40, 80 and 160 meters. For this reason there are vernier-drive dials on C1 and C2. They are also useful in logging the dial settings for changing bands or antennas.

### Construction

Figs. 32 and 35 show the structural details of the Transmatch. The cabinet is homemade from 16-gauge aluminum sheeting. L brackets are affixed to the right and left sides of the lower part of the cabinet to permit attachment of the U-shaped cover.

The conductors which join the components should be of heavy-gauge material to minimize stray inductance and heating. Wide strips of flashing copper are suitable for the conductor straps. The center conductor and insulation from RG-59 polyfoam coaxial cable is used in this model for the wiring between the switch and the related components. The insulation is sufficient to prevent breakdown and arcing at 2 kW PEP input to the transmitter.

All leads should be kept as short as possible to help prevent degradation of the cir-

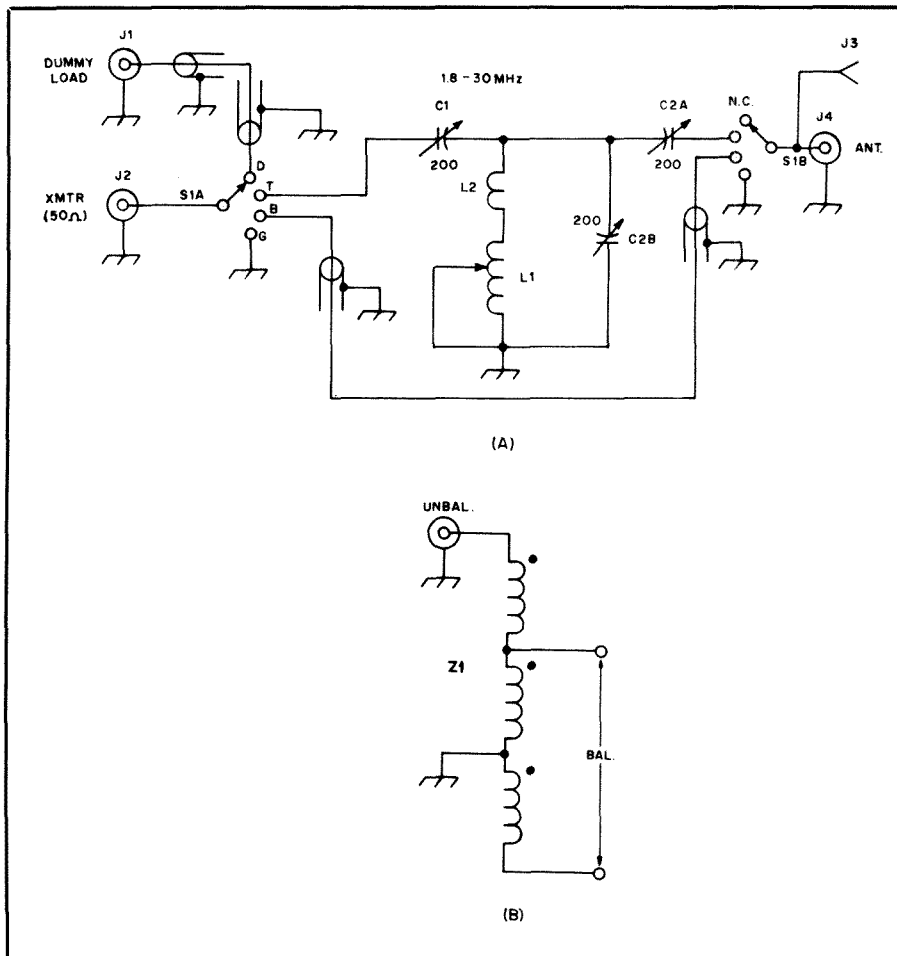

Fig. 34 — Schematic diagram of the SPC circuit. Capacitance is in picofarads.

C1 — 200-pF transmitting variable with plate spacing of 0.075 inch or greater. J. W. Miller Co. no. 2150 used here.

C2 — Dual-section variable, 200 pF per section. Same plate spacing as C1. J. W. Miller Co. no. 2151 used here. (Catalog no. 79, J. W. Miller Co., 19070 Reyes Ave., Compton, CA 90224.)

J1, J2, J4 — SO-239 style coaxial connector.

J4 should have high-dielectric insulation if high-Z single-wire antennas are used at J3. Teflon insulation is recommended.

J3 — Ceramic feedthrough bushing.

L1 — Rotary inductor, 25  $\mu$ H min. inductance. E. F. Johnson 229-203 or equiv.

L2 — Three turns no. 8 copper wire, 1 inch ID  $\times$  1 1/2 inches long.

S1 — Large ceramic rotary wafer switch with heavy contacts. Two-pole, 4-position type. Surplus Centralab JV-9033 or equiv., two positions unused.

Z1 — Balun transformer. 12 turns no. 12 Formvar wire, trifilar, close-wound on 1-inch-OD phenolic or PVC-tubing form.

cuit Q. The stators of C1 and C2 should face toward the cabinet cover to minimize the stray capacitance between the capacitor plates and the bottom of the cabinet (important at the upper end of the Transmatch frequency range). Insulated ceramic shaft couplings are used between the vernier drives and C1 and C2, since the rotors of both capacitors are floating in this circuit. C1 and C2 are supported above the bottom plate on steatite cone insulators. S1 is at-

Fig. 35 — Interior view of the W1FB SPC Transmatch. L2 is mounted on the rear wall by means of two ceramic standoff insulators. C1 is on the right and C2 is at the left. The coaxial connectors, ground post and J3 are on the lower part of the rear panel.

tached to the rear apron of the cabinet by means of two metal standoff posts.

### Operation

The SPC Transmatch is designed to handle the output from transmitters which operate up to 2 kW PEP input. L2 has been added to improve the circuit Q at 10 and 15 meters. However, it may be omitted from the circuit if the rotary inductor (L1) has a tapered pitch at the minimum-inductance end. It may be necessary to omit L2 if the stray wiring inductance of the builder's version is high. Otherwise, it may be impossible to obtain a matched condition at 28 MHz with certain loads.

An SWR indicator is used between the transmitter and the Transmatch to show when a matched condition is achieved. The builder may want to integrate an SWR meter in the Transmatch circuit between J2 and the arm of S1A (Fig. 34A). If this is

done there should be room for an edgewise panel meter above the vernier drive for C2.

Initial transmitter tuning should be done with a dummy load connected to J1, and with S1 in the D position. This will prevent interference which could otherwise occur if tuning is done on the air. After the transmitter is properly tuned into the dummy load, unkey the transmitter and switch S1 to T (Transmatch). Never hot switch a Transmatch, as this can damage both transmitter and Transmatch. Set C1 and C2 at midrange. With a few watts of RF, adjust L1 for a decrease in reflected power. Then adjust C1 and C2 alternately for the lowest possible SWR. If the SWR cannot be reduced to 1:1, adjust L1 slightly and repeat the procedure. Finally, increase the transmitter power to maximum and touch up the Transmatch controls if necessary. When tuning, keep your transmissions brief and identify your station.

The air-wound balun of Fig. 34B can be

used outboard from the Transmatch if a low-impedance balanced feeder is contemplated. Ferrite or powdered-iron core material is not used in the interest of avoiding TVI and harmonics that can result from core saturation.

The B position of S1 permits switched-through operation when the Transmatch is not needed. The G position is used for grounding the antenna system, as necessary; a quality earth ground should be attached at all times to the Transmatch chassis.

### Final Comments

Surplus coils and capacitors are okay in this circuit. L1 should have at least 25  $\mu$ H of inductance, and the tuning capacitors need to have 150 pF or more of capacitance per section. Insertion loss through this Transmatch was measured at less than 0.5 dB at 600 watts of RF power on 7 MHz.

## A Link-Coupled Matching Network

Link coupling offers many advantages over the types of systems where a direct connection between the transmitter and antenna is required. This is particularly true on 80 meters, where commercial broadcast stations often induce sufficient voltage to cause either rectification or front-end overload. Transceivers and receivers that show this tendency can usually be cured by using only magnetic coupling between the transceiver and antenna system. There is no direct connection and better isolation results along with the inherent band-pass characteristics of magnetically coupled tuned circuits.

Although link coupling can be used with either single-ended or balanced antenna systems, its most common application is with balanced feed. The model shown here is designed for 80- through 10-meter operation.

### The Circuit

The circuit shown in Fig. 37 and the accompanying photographs are those of a band-switched link coupler. L2 is the link and C1 is used to adjust the coupling. S1B

Fig. 36 — Exterior view of the band-switched link coupler. Alligator clips are used to select the proper tap positions of the coil.

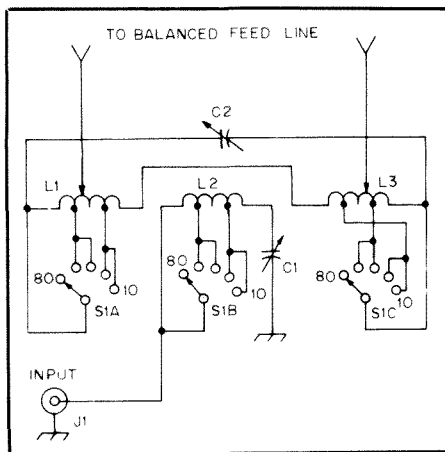

Fig. 37 — Schematic diagram of the link coupler. The connections marked as "to balanced feed line" are steatite feedthrough insulators. The arrows on the other ends of these connections are alligator clips.

C1 — 350 pF maximum, 0.0435 inch plate spacing or greater.

C2 — 100 pF maximum, 0.0435 inch plate spacing or greater.

J1 — Coaxial connector.

L1, L2, L3 — B&W 3026 Miniductor stock, 2-inch diameter, 8 turns per inch, no. 14 wire. Coil assembly consists of 48 turns.

L1 and L3 are each 17 turns tapped at 8 and 11 turns from outside ends. L2 is 14 turns tapped at 8 and 12 turns from C1 end. See text for additional details.

S1 — 3-pole, 5-position ceramic rotary switch.

Fig. 38 — Interior view of the coupler showing the basic positions of the major components. Component placement is not critical, but the unit should be laid out for minimum lead lengths.

selects the proper amount of link inductance for each band. L1 and L3 are located on each side of the link and are the coils to which the antenna is connected. Alligator clips are used to connect the antenna to the coil because antennas of different impedances must be connected at different points (taps) along the coil. With many antennas it will be necessary to change taps for different bands of operation. C2 tunes L1 and L3 to resonance at the operating frequency.

Switch sections S1A and S1C select the amount of inductance necessary for each of the HF bands. The inductance of each of the coils has been optimized for antennas in the impedance range of roughly 20-600 ohms. Antennas that exhibit impedances well outside this range may require that some of the fixed connections to L1 and L3 be changed. Should this be necessary remember that the L1 and L3 sections must be kept symmetrical — the same number of turns on each coil.

### Construction

The unit is housed in a homemade

aluminum enclosure that measures  $9 \times 8 \times 3\frac{1}{2}$  inches. Any cabinet with similar dimensions that will accommodate the components may be used. L1, L2 and L3 are a one-piece assembly of B&W 3026 Miniductor stock. The individual coils are separated from each other by cutting two of the turns at the appropriate spots along the length of the coil. Then, the inner ends of the outer sections are joined by a short wire that is run through the center of L2. Position the wire so that it will not come into contact with L2. Each of the fixed tap points on L1, L2 and L3 is located and lengths of hookup wire are attached. The coil is mounted in the enclosure and the connections between the coil and the band-switch are made. Every other turn of L1 and L3 is pressed in toward the center of the coil to facilitate connection of the alligator clips.

As can be seen from the schematic, C2 must be isolated from ground. This can be accomplished by mounting the capacitor on steatite cones or other suitable insulating material. Make sure the hole through the

front panel for the shaft of C2 is large enough so the shaft does not come into contact with the chassis.

### Tuneup

The transmitter should be connected to the input of the Transmatch through some sort of instrument that will indicate SWR. S1 is set to the band of operation and the balanced line is connected to the insulators on the rear panel of the coupler. The alligator clips are attached to the mid points of coils L1 and L3 and power is applied. Adjust C1 and C2 for minimum reflected power. If a good match is not obtained, move the antenna tap points either closer to the ends or center of the coils. Again apply power, and tune C1 and C2 until the best possible match is obtained. Continue moving the antenna taps until a 1-to-1 match is obtained.

The circuit described here is intended for power levels up to roughly 200 watts. Balance was checked by means of two RF ammeters, one in each leg of the feed line. Results showed the balance to be well within 1 dB.

# A Balanced QRP Transmatch

The balanced QRP Transmatch shown in Figs 39 through 41 was designed and built by Zachary Lau, KH6CP, in the ARRL Lab. It is designed for use with balanced feed lines, although random-wire antennas can be fed if one of the antenna terminals is grounded. Unlike most Transmatches designed for use with balanced feed lines, this design features a balun at the input, rather than at the output. As a result, the balun sees impedances close to the design impedances once the Transmatch has been properly adjusted. This results in lower loss and freedom from core saturation at low power levels.

Since it is balanced currents that prevent feed-line radiation, this circuit was designed to balance currents rather than voltages. Some antenna systems use circuits that provide balanced voltages, making it necessary to make the system symmetrical in an effort to balance the currents. By going straight to balanced currents, instead of balanced voltages, it is possible to use a much simpler matching network. In addition, the actual current balance in typical amateur open-wire feed lines should be improved.

## Construction

The inductor L1 and the capacitor C1 should be of the highest quality obtainable for best performance. Low-impedance loads will require a good inductor for efficient matching, while high-impedance loads will require a good capacitor.

L1 was wound with tinned copper wire to make it easier to adjust taps. It is necessary to wind the wire with spaces between turns to prevent shorts which may make the inductor lossy; no. 16 wire is heavy enough to stay in position on the toroid. The inductor used had a full-inductance Q of 420 at 7.9 MHz; the Q was 410 after the taps and switch were added. The use of clip lead taps is not recommended as they increase losses, although they may be useful in initially setting up tap positions.

Capacitor C1 should have a value of at least 250 pF, and larger capacitors will work even better, increasing the range of the Transmatch at low frequencies. Suitable capacitors are usually available at hamfests. The value of C2 and C3 should equal C1, and C4 should be twice the value of C1. If the calculated values of C2, C3 and C4 are not available, smaller values may be used.

Capacitor C1 must be insulated from the chassis, so it was mounted using ½-inch Plexiglas® with tapped screw holes. An insulated shaft coupler was used to prevent high voltage from appearing on the knob set screw. The cabinet is a Ten-Tec MW-8 with a model 91-206 matching tilt-up bail. Although it is large for a QRP Transmatch, the cabinet matches the author's QRP rig

Fig 39 — This QRP Transmatch for balanced feed lines features a balun at the input of the matching network.

and allows the controls to be spaced apart for easy use. The logging scale is type-written paper attached to the cabinet with a Plexiglas sheet.

T1 is a trifilar-wound transformer.

Winding details are shown in Fig 40. It is possible to wind this coil with only two windings, eliminating the solder joint. The coil should be duplicated exactly with regard to the number of turns and core

material unless the transformer can be tested at the operating frequency. Testing can be done by hooking up two baluns in series and measuring the insertion loss. The matching network will compensate for a poor balun, but efficiency will probably suffer. A toroidal choke balun would be recommended for a higher power version.

Switches S1 and S2 should be ceramic. Phenolic switches are not recommended, although they should work at low power levels on the order of a few watts. The switch positions should never be changed while more than a few watts of RF is applied.

### Adjustment

Adjustment of the Transmatch is much easier if the approximate impedance of the load is known. In his article in *The ARRL Antenna Compendium, Volume 1*, "Mr. Smith's 'Other' Chart and Broadband Rigs" Roger Ghormley, W0KK, details how parts values for L networks can be calculated. Alternately, received signals can be peaked up by first adjusting the inductor and then the capacitor. As with any Transmatch, low power should be used in the initial adjustment. The actual power handling capability will depend on the load. The capacitor breakdown voltage is the limiting factor on high-impedance loads; a 2000-ohm load will cause the 500 V capacitors to reach their maximum rating at 62.5 W, while the maximum rating will be reached with 625 watts into a 200-ohm load. The current-handling capability of the wire is the limit on low-impedance loads;

a 40-ohm load will cause a 90-W signal to generate 1.5 A through the wire, while 450 watts will generate 1.5 A if the load is 200 ohms. These values are for resistive

loads; a reactive load would require higher current and voltage ratings. The unit shown here has worked well in low-power operation (up to 4.5 watts).

Fig. 41 — Interior layout of the QRP Transmatch. The variable capacitor is mounted on a Plexiglas block.

# A 50- to 75-Ohm Broadband Transformer

Shown in Figs. 42 through 44 is a simple 50- to 75-ohm or 75- to 50-ohm transformer that is suitable for operation in the 2- to 30-MHz frequency range. A pair of these transformers is ideal for using 75-ohm CATV hardline in a 50-ohm system. In this application one transformer is used at each end of the cable run. At the antenna one transformer raises the 50-ohm impedance of the antenna to 75 ohms, thereby presenting a match to the 75-ohm cable. At the station end a transformer is used to step the 75-ohm line impedance down to 50 ohms.

The schematic diagram of the transformer is shown in Fig. 42, and the winding details are given in Fig. 43. C1 and C2 are compensating capacitors; the values shown were determined through swept return-loss measurements using a spectrum analyzer and tracking generator. The transformer consists of a trifilar winding of no. 14 enameled copper wire wound over an FT-240-61 (Q1 material) or equivalent core. As shown in Fig. 43, one winding has only half the number of turns of the other two. Care must be taken when connecting the loose ends so the proper phasing of the turns is maintained. Improper phasing will become apparent when power is applied to the transformer.

If the core has sharp edges it is a good idea either to sand the edges until they are relatively smooth or wrap the core with tape. The core shown in the photograph was wrapped with ordinary vinyl electrical tape, although glass-cloth insulating tape

would be better. The idea is to prevent chafing of the wire insulation.

## Construction

The easiest way to construct the transformer is wind the three lengths of wire on the core at the same time. Different color wires will aid in identifying the ends of the windings. After all three windings are securely in place, the appropriate wire may be unwound three turns as shown in the diagram. This wire is the 75-ohm connection point. Connections at the 50-ohm end are a bit tricky, but if the information in Fig. 43 is followed carefully no problems should be encountered. Use the shortest connections possible, as long leads will degrade the high-frequency performance.

The transformer is housed in a home-made aluminum enclosure measuring  $3\frac{1}{2} \times 3\frac{3}{4} \times 1\frac{1}{4}$  inches. Any commercial cabinet of similar dimensions will work fine. In the unit shown in the photograph, several "blobs" of silicone seal (RTV) were used to hold the core in position. Alternatively, a piece of phenolic insulating material may be used between the core and the aluminum enclosure. Silicone seal is used to protect the inside of the unit from moisture. All joints and screw heads should receive a generous coating of RTV.

## Checkout

Checkout of the completed transformer or transformers is quite simple. If a 75-ohm dummy load is available connect it to the 75-ohm terminal of the transformer. Connect a transmitter and SWR indicator (50 ohm) to the 50-ohm terminal of the transformer. Apply power (on each of the HF bands) and measure the SWR looking into the transformer. Readings should be well under 1.3 to 1 on each of the bands. If a 75-ohm load is not available and two transformers have been constructed they may be checked out simultaneously as follows. Connect the 75-ohm terminals of both transformers together, either directly through a coaxial adaptor or through a length of 75-ohm cable. Attach a 50-ohm load to one of the 50-ohm terminals and connect a transmitter and SWR indicator (50 ohm) to the remaining 50-ohm terminal. Apply power as outlined above and record the measurements. Readings should be under 1.3 to 1.

The transformers were checked in the ARRL laboratory under various mismatched conditions at the 1500-watt power level. No spurious signals (indicative of core saturation) could be found while

viewing the LF, HF and VHF frequency range with a spectrum analyzer. A key-down, 1500-watt signal produced no increase in the temperature of the windings.

## Using the Transformers

For indoor applications, the transformers can be assembled open style, without benefit of a protective enclosure. For outdoor installations, such as at the antenna feed point, the unit should be encapsulated in epoxy resin or mounted in a suitable weatherproof enclosure. A Mini-box, sealed against moisture, works nicely for the latter.

# Super Dummy

Super Dummy is an RF load for use with full-power RF amplifiers. See Figs. 45 through 49. Designed by ARRL TA Dick Jansson, WD4FAB, this dummy load will "loaf" along at 1500 watts for 10 minutes without complaint. Super Dummy is not just a copy of the similar appearing Heathkit® HN-31A Cantenna. A lot of development went into proving this design. These efforts concentrated on RF matching, heat transfer design and coolant selection.

It is not easy to design a dummy load for high-power operation. Heat must be safely dissipated and a good match maintained. Forced air cooling of 300 two-watt carbon resistors and running a Heath Cantenna with automobile antifreeze coolant were tried. Neither of these ideas proved satisfactory. Efforts were then turned to other directions. An improved dummy load evolved from this work. Super Dummy is suitable for HF and low VHF regions at 1500 watts.

The Bird Model 612 dummy load/wattmeter uses the type of construction shown in Fig. 46. This design ensures proper characteristic impedance ( $Z_0$ ) along the structure. Starting with the coaxial connector, a tapered line is used to provide a constant impedance (50 ohms) to the resistor. The coaxial shield then decreases in size to

Fig. 46 — An RF load should have proper characteristic impedance along the entire structure for operation over a wide frequency range. See text.

match the diminishing impedance to ground along the resistor. Coaxial line impedance can be determined from the formula:

$$Z_0 = \frac{138}{\sqrt{\epsilon}} \log \frac{D}{d}$$

where

- $Z_0$  = coaxial line characteristic impedance
- $D$  = ID of coaxial shell
- $d$  = OD of coaxial conductor
- $\epsilon$  = dielectric constant of coolant (air = 1.0)

This equation shows that as the impedance along the resistor diminishes following a straight-line curve, the shape of the coaxial shield or shell around the resistor follows a smooth logarithmic curve. That curve can be seen in Fig. 46.

A logarithmically tapered coaxial shell is difficult to form. At HF, we don't have to worry about the shape of the coaxial shell. Unless you are a purist, it is far easier to just use the straight tubing shown in Figs. 47 and 48. A straight shell proves quite usable into the VHF region. For a 50-ohm resistor, the coaxial shell is sized for a  $Z_0$  of about 25 ohms.

## RF Performance

The SWR of Super Dummy was measured in the ARRL lab. Fig. 49 shows the results, an excellent match through the HF region (SWR less than 1.05). SWR is only 1.08 at 50 MHz, rising to a tolerable 1.4 at 144 MHz.

## Construction

Construction of Super Dummy is straightforward. Two one-gallon paint cans were obtained from a painting supply house. A 5.5-inch-diameter disc is removed from the closed end of the top can and four 0.120-inch holes are drilled equally spaced through the remaining bottom rim with matching holes in the top rim of the bottom can. The two cans can now be locked together with four no. 4 screws and nuts,

forming a "two high" can assembly. Carefully solder the rims of the cans to fully seal the assembly against oil leakage. Be sure to secure the cans with the screws as solder is dependable only for sealing and not for mechanical strength.

Mount the shield tube to the cover with four aluminum angle brackets. Space the tube 1.5 to 2 inches from the cover, allowing room for the coolant to flow out of the top. Clamp the copper straps to each end of the resistor. Under the top strap be sure to include the U-shaped strap that is used to connect the resistor and the SO-239 coaxial connector. Install the resistor in the tube, making sure that the U strap slides over the SO-239 connector center pin. Center and clamp the lower end firmly with four no. 6 brass screws and lock nuts. Solder the U strap to the connector pin after clamping the lower end.

## Coolant

Selection of a coolant for the resistor involved a lengthy investigation. The use of PCB transformer oils is illegal and involves a serious health hazard. The investigation did identify several modern-day transformer and heat transfer oils that could be used, but none of these are available for purchase in any quantity less than a 55-gallon drum.<sup>1</sup> Transformer oil has lower viscosity. That means lower resistor temperatures, but at the penalty of using an oil with a 140 to 150°C flash point (vaporization temperature). Transformer oils are also treated to remove water, but maintaining this dry condition is difficult and expensive. Calculations of the fluid heat transfer show that turbulent nature convection flow exists for rated power levels. The use of higher viscosity oil produces higher resistor temperatures, but the gain in flash point temperature is greater than the rise in resistor temperature. Oils designed for heat transfer have flash points in the 230 to 250°C region.

<sup>1</sup>Shell Oil Co., "Thermia"; Chevron Oil Co., "Heat Transfer Oil No. 1"; Gulf Oil Co., Security No. 53; Texas Oil Co., "Thermia".

Fig. 45 — Super Dummy is an RF load designed to handle 1.5 kW.

Fig. 47 — X-ray view of the interior of Super Dummy. To ensure proper cooling, coolant level should be higher than the top of the tube.

Heat transfer oils are composed predominantly of mineral oil. Highly refined or medicinal mineral oil has a useably high flash point but an undesirably high cost. Heat transfer oils contain small amounts of rust and oxidation inhibitors, making them preferable to mineral oils. Heat transfer oils are not available in small quantities, but in at least one case the very same product is relabeled and sold in 5 gallon cans for service as a "turbine oil." That product is sold by TEXACO distributors as Regal Oil R&O No. 46.

Use of automotive motor and transmission oils is undesirable. They are composed of a wide mixture of oils with differing flash points. Motor oil additives will damage the metal platings on an RF resistor. There is no danger in the short term use of automotive oils, but the long-term

Fig. 48 — View of the insides of Super Dummy. Construction details are given in Fig. 47.

Fig. 49 — Super Dummy SWR curve. Measurements were made in the ARRL lab using swept return-loss techniques.

effects are a problem. Further, there are no economic advantages with automotive oils, as they cost as much as turbine oil.

#### Thermal Tests

Thermal performance tests were done with Super Dummy in mineral oil at a power level of 1.5 kW. The large resistor used in Super Dummy has a reasonable power density ( $3.5 \text{ watts/cm}^2$ ).<sup>2</sup> That

<sup>2</sup>Carborundum 889SP500K. Available in single quantities from Radiokit, P.O. Box 973, Pelham, NH 03076 (tel 603-635-2235). Also available from The Carborundum Co., Electric Products Div., P.O. Box 339, Niagara Falls, NY 14302.

results in moderate operating temperatures and negligible resistance shift. Some tests were conducted without the coaxial shield tube. Considerable thermal stagnation of the oil was measured in these tests with temperatures in the range of  $160^\circ\text{C}$  at the top and only  $40^\circ\text{C}$  at the bottom of the container. The coaxial shield tube around the resistor performs another valuable function here. The tube enhances oil flow from the bottom of the can to the top, forcing better oil mixing in the can and effective use of the total thermal mass of the 2 gallons of coolant.

# UHF Gallon Dummy

UHF Gallon Dummy is an RF load for use with VHF and UHF RF amplifiers up to 1.3 GHz and power outputs to 1 kW. See Figs. 50 through 58. Designed by ARRL TA Dick Jansson, WD4FAB, this dummy load is an extension of the work done with "Super Dummy," the HF legal-limit load presented earlier in this chapter. It will handle 1000 watts for five minutes without complaint. A lot of development went into proving this design, with efforts concentrated on RF matching, heat transfer design and coolant selection.

The Bird Model 612 dummy load/wattmeter uses the type of construction shown in Fig. 46. This design ensures proper characteristic impedance ( $Z_0$ ) along the structure. Starting with the coaxial connector, a tapered line is used to provide a constant impedance (50 ohms) to the resistor, while expanding the transmission line size up to meet that of the resistor. The coaxial shield then decreases in size along the resistor to match the diminishing impedance-to-ground of the resistor. Coaxial line impedance can be determined from the formula

$$Z_0 = \frac{138}{\sqrt{\epsilon}} \log \frac{D}{d}$$

where

$Z_0$  = coaxial line characteristics impedance

$D$  = ID of coaxial shell

$d$  = OD of coaxial conductor

$\epsilon$  = dielectric constant of coolant (air = 1.0).

This equation shows that as the impedance along the resistor diminishes following a straight-line curve; the shape of the coaxial shield or shell around the resistor follows a smooth logarithmic curve. That curve can be seen in Fig. 46.

A logarithmically tapered coaxial shell is difficult to form, so most designers just use straight tubing at HF. This approach works just fine. For the VHF and UHF region, however, proper RF impedance matching is very important because the dimensions of the load become significantly sizable compared to the wavelengths of interest. UHF Gallon Dummy provides a close approach to the ideal shapes.

## RF Performance

The SWR of the UHF Gallon Dummy was measured in the ARRL lab. Fig. 51 shows the results: An excellent match through 220 MHz (SWR less than 1.05). SWR is a tolerable 1.25 for the 70-cm band and less than 1.25 for the 23-cm band. To obtain these results, you *must* have UHF Gallon Dummy immersed in its coolant oil. The dielectric constant of the oil is approximately 2.3. UHF Gallon Dummy tested dry showed an SWR of approximately 2.0 across most of the spectrum. The change

is caused by the difference between the dielectric constant of the oil and that of air.

Deviations in performance from the target design are caused by some of the practicalities of constructing such a load. The builder can carefully watch, and avoid, such elements as the dimensional steps in the center conductor as it attaches to the connector, and at the junction with the resistor. The lack of a logarithmically shaped resistor shell will, of course, pro-

vide an element of performance error. In short, paying attention to small details is important in obtaining the best performance from this load.

## Construction

Although you can build the UHF dummy load shown here from parts purchased separately from suppliers, a good way to begin is to purchase a Heathkit® HN-31A "Cantenna" dummy load and modify it. This way, you won't have to track down the power resistor, and you'll get one of the paint cans complete with a lid with a vent hole.

The housing for the UHF Gallon Dummy is made from two one-gallon paint cans obtained from a painting supply house. Remove a 5.5-inch-diameter disc from the closed (bottom) end of the top can. Drill four 0.120-inch holes, equally spaced, around the remaining bottom rim; drill matching holes in the top rim of the bottom can. The two cans can now be locked together with four no. 4 screws and nuts, forming a "two high" can assembly. Carefully solder the rims of the cans to fully seal the assembly against oil leakage. You must secure the cans with the screws, as solder is only dependable for sealing and not for mechanical strength. Prime and paint the exterior of this can assembly to resist the rigors of rust corrosion.

The interior parts of the UHF Gallon Dummy were built using hobby store brass shim stock, a 1-kW (rating with coolant) 50-ohm resistor (available from Carborundum<sup>1</sup> or from a Heathkit HN-31A) and

Fig. 50 — UHF Gallon Dummy is built into two one-gallon paint cans bolted and soldered together.

<sup>1</sup>Carborundum 886SP500K. Available from The Carborundum Co., Electric Products Div., P.O. Box 339, Niagara Falls, NY 14302.

Fig. 51 — UHF Gallon Dummy SWR curve made in the ARRL lab using swept return-loss techniques. Measurements were made in the two-gallon can with turbine oil coolant.

some wooden dowels. Apart from an electric drill and a soldering iron, this double conical shape was formed entirely with hand tools. Fig. 52 is an X-ray view of the interior of the UHF Gallon Dummy showing the arrangement of the parts.

Make all of the parts before you begin assembly of any part of the load. Figs. 53 and 54 detail the flat layout of the sheet brass that will be used to make the transition and resistor cones. Fig. 55 shows the center-conductor cone, four braces and two clamp bands. These drawings are full-size templates. They may be photocopied and used directly to do the sheet-metal layout. Carefully lay out and cut these parts to size. Drill the no. 60 holes and cut the joining tabs.

Start assembly by forming the brass stock for the transition cone into a conical shape. The edges of the brass stock are lap-joined and soldered along the longitudinal seam. You will get better results if you drill some small holes in the tab where the two edges overlap and install 1/16-inch eyelets to act as rivets to hold the assembly together as you solder. Assemble the resistor cone the same way. Assembly of the conical copper center conductor is similar, except that it is just soldered along its seam (no rivets). Figs. 56 and 57 show how the pieces should look when finished and how they will attach to the paint can lid.

Drill a hole for the UG-680 hermetic Type-N connector in the center of the paint can lid. Attach the connector nut and securely tighten it in place. Solder the connector to top of the lid, as shown in Fig. 58, to seal the connection against possible coolant leakage.

Solder the small end of the brass transition cone to a shortened nut from a PL-259 connector. This nut will screw onto the back-side threads of the UG-680 connector. Be sure to drill a small vent relief hole through the PL-259 nut to allow coolant oil into the upper section of cone; see Fig. 56. Check this assembly on the UG-680 to be sure that it is perpendicular to the lid, but do not attach yet.

Clamp the large end of the conical center conductor to the resistor and check that it is straight and true. Check the small end of the center-conductor tube for fit on the UG-680 center conductor. Slide this cone-and-resistor subassembly into the brass transition shell; leave it loose. Carefully line up the tabs on the large end of the transition cone with the tabs on the large end of the resistor cone. When you are sure of the alignment, solder the tabs together to form one large double-conical shell. The cone-and-resistor subassembly will still be a loose part inside the shell assembly.

Slide the small end of the center-conductor cone through the small end of the transition cone and solder it to the center conductor of the UG-680 connector. Screw the double-cone shell assembly to the outside of the UG-680 connector. When the connector end is in place, the free end of

Fig. 52 — Cutaway view of UHF Gallon Dummy.

the resistor should fit into the small end of the resistor cone, where it will be secured with a brass clamp band.

Add the four braces by soldering them between the lid and the transition cone to make a more rigid structure. Check your work at this point and make any corrections.

#### Coolant

Selection of a coolant for the resistor involved a lengthy investigation. The use of PCB transformer oils is illegal and involves a serious health hazard. The investigation did identify several modern-day transformer and heat transfer oils that could be used, but none of these are available for purchase in any quantity less than a 55-gallon drum.<sup>2</sup> Transformer oil has lower

viscosity. That means lower resistor temperatures, but at the penalty of using an oil with a 140 to 150°C flash point (vaporization temperature). Calculations of the fluid heat transfer show that a turbulent natural convection flow exists for rated power levels. The use of higher viscosity oil produces higher resistor temperatures, but the gain in flash point temperature is greater than the rise in resistor temperature. Oils designed for heat transfer have flash points in the 230 to 250°C region. Transformer oils are treated to remove water, but maintaining this dry condition is difficult and expensive.

Heat transfer oils are composed mainly of mineral oil. Highly refined or medicinal mineral oil has a usable high flash point but an undesirably high cost. Heat transfer oils contain small desirable amounts of rust and oxidation inhibitors, making them preferable to mineral oils. Heat transfer oils are not available in small quantities, but in at

least one case the very same product is relabeled and sold in 5 gallon cans for service as a "turbine oil." That product is sold by the Texas Oil Company (TEXACO) distributors as Regal Oil R&O No. 46.

Use of automotive motor and transmission oils is undesirable. They are composed of a wide mixture of oils with differing flash points. Motor oil additives will damage the metal platings on an RF resistor. There is no danger in the short term use of automotive oils, but the long term effects are a problem. There are no economic advantages with automotive oils either; they cost just as much as turbine oil.

#### Thermal Tests

Thermal performance tests were done with the UHF Gallon Dummy with a 1-kW resistor (rating with coolant) in mineral oil at a power level of 1.5 kW. The tests were conducted with considerable apprehension, but no spectacular events occurred except for very vigorous convection flow of oil over the resistor. Don't use this size resistor at higher power levels than its 1 kW (cooled) rating. The resistor gets *very hot* at 1.5 kW, and substantial permanent resistance shifts have been measured.

Some tests were conducted without a coaxial shield tube. Considerable thermal stagnation of the oil was measured in these tests with temperatures in the range of 160°C at the top and only 40°C at the bottom of the container. The coaxial shield assembly at the top and only 40°C at the bottom of the container. The coaxial shield assembly around the resistor performs another valuable function here. The shield enhances oil flow from the bottom of the can to the top, forcing better oil mixing in the can and effective use of the total thermal mass of the two gallons.

## A Marker Generator for 100, 50 and 25 kHz

A marker generator that provides reference signals at 100-, 50-, and 25-kHz intervals is a useful addition to any ham shack. The generator can be used as a low-level signal source when testing receivers, or it can be installed inside a receiver and used to mark the edges of the amateur bands and subbands. When built into a receiver, the marker generator is usually called a crystal calibrator.

The standard design for a marker generator involves using a crystal oscillator operating at 100 kHz and then dividing this signal with flip-flops to get the 50- and 25-kHz signals. The 100-kHz crystals are rather expensive, however, and are difficult to locate.

Another way to produce marker signals is to use a crystal oscillator operating at a multiple of 1 MHz. Crystals for 1, 2 and 4 MHz are readily available at reasonable prices on the computer surplus market.

Fig. 63—Front view of the 100-, 50- and 25-kHz marker generator. A two-pole rotary switch was used in this unit; one section of the switch was used to apply power to the generator, and the other section was used to select the desired signal. Another builder may wish to use a separate power switch and/or LED power indicator.

Low-cost TTL ICs can then be used to divide the signal down to 100, 50 and 25 kHz. This is the approach taken in the marker generator shown in Figs. 63 through 66. The marker generator is simple to build, and it provides a good introduction to the principles of digital circuits. The output of the generator is rich in harmonics and provides marker signals up into the 2-meter band. This project was designed and built by Bruce Hale, KB1MW, in the ARRL Lab.

### Circuit Description

The schematic of the marker generator is shown in Fig. 64. Two of the NAND gates in a 7400 quad-NAND package, U1, are used as an oscillator. The crystal, Y1, sets the operating frequency at 1, 2 or 4 MHz, and C1 is used to trim the frequency during the calibration procedure. U1C acts as a buffer between the oscillator and the rest

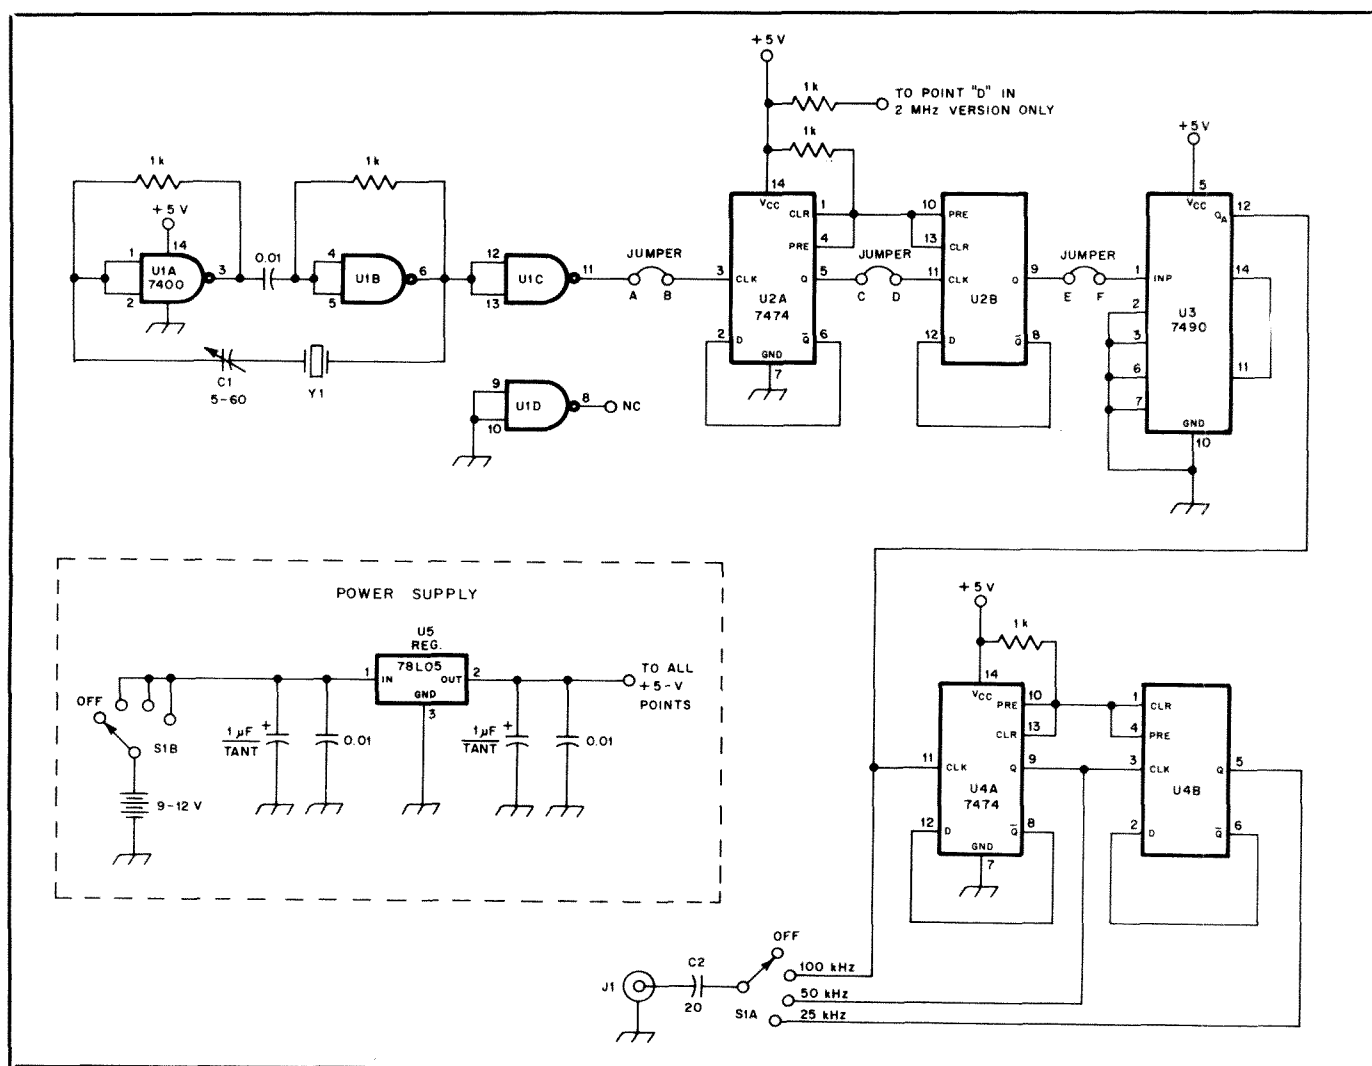

Fig. 64—Schematic diagram of the marker generator. All resistors are  $\frac{1}{4}$ -W, 5% types. All capacitors are disk ceramic unless noted. Capacitors marked with polarity are tantalum electrolytic.

J1 — Female, chassis-mount BNC connector,

U1—7400 or 74LS00 quad NAND gate.  
U2, U4—7474 or 74LS74 dual D flip-flop.

U3—7490 or 74LS90 decade counter.  
U5—78L05 or 7805 5-V regulator (see text).  
Y1—1, 2 or 4-MHz crystal in HC-25, HC-33 or HC-6 holder.

Fig. 65—The marker generator may be built using a 1 MHz, 2 MHz or 4 MHz crystal. With a 1 MHz crystal, U2 is not needed. The 4-MHz version was built using a 7805 regulator. All the units built in the ARRL lab could be trimmed to within 50 Hz of 100 kHz, including a prototype built on perforated board.

of the circuit; U1D is not used, so its inputs are grounded. Unused TTL gate inputs should always be connected either to ground or to  $V_{cc}$  through a pull-up resistor.

U2 is a 7474 dual D flip-flop. The two flip-flops in this package are used to divide the output of the oscillator down to 1 MHz. This circuit is designed so that crystals operating at 1, 2 or 4 MHz can be used, depending on what is available. If a 1-MHz crystal is used, U2 is not needed and can be left completely out of the circuit. If a 2-MHz crystal is used, one flip-flop of the two available is used, and the input of the second flip-flop is pulled high with a 1-k $\Omega$  resistor. Using a 4-MHz crystal requires both flip-flops for a 1-MHz output to U3. Notice the PRESET and CLEAR inputs (pins 1, 4, 10 and 13); these inputs can be pulled low to set and clear the flip-flops. During normal operation these inputs must be held high—a 1-k $\Omega$  pull-up resistor is connected from the PRESET and CLEAR inputs to  $V_{cc}$ .

U3 is a 7490 divide-by-ten counter (sometimes called a decade counter). A 1 MHz input to this IC produces a 100 kHz output signal at pin 12. We could stop here if we were building a 100-kHz signal generator.

Another 7474 dual flip-flop is used at U4 to divide the 100-kHz output of U3 down to 50 and 25 kHz. Again, the PRESET and CLEAR inputs must be pulled high. The outputs of U3, U4A and U4B are connected to switch S1A to select the desired output. C2 decouples the output jack from the circuit to prevent excessive loading.

U5 is a 78L05 low-current, 5-V regulator IC in a TO-92 package. The regulator input and the output are bypassed with 1- $\mu$ F tantalum and 0.01- $\mu$ F disc ceramic capacitors. A 9-V transistor battery provides the power source, and S1B is used as an on-off switch.

## Construction

Construction of this project is straight-

forward. A PC board was used in the final versions shown in Fig. 65, but a prototype built on a Radio Shack perforated board worked well. Wire-wrap construction could also be used.

A PC component-placement diagram is shown in Fig. 66. The PC pattern shown can be used to build the marker generator using any of the three crystal frequencies by varying the placement of three jumper wires. Locations for the jumpers are clearly labeled on the PC pattern and they should be set as shown in Table 1, depending on the crystal frequency. Provision is made on the PC board for either crystals in small

Table 1

## Marker Generator Jumper Placement

Crystal Frequency	Jumper Placement
1 MHz	A—F U2 not used
2 MHz	A—B, C—F Add a 1-k $\Omega$ resistor from D to U2 pin 14
4 MHz	A—B, C—D, E—F

HC-25 holders or the larger HC-33 or HC-6 holders.

If low-power Schottky ICs are available, they should be used at U1, U2, U3 and U4. These ICs draw considerably less current than their standard TTL counterparts, and using them will reduce the drain on the battery. These devices are labeled with "LS" as part of their numerical designator; a low-power quad NAND gate is designated a 74LS00.

The value of the coupling capacitor, C2, is not critical. Any value between 10 and 100 pF will work, with the larger values providing a bit less signal at the output jack.

A standard 7805 regulator IC in a TO-220 package can be used at U5 if a 78L05 cannot be located. This is "overkill" in a way, since the 7805 is rated to pass at least an amp of current, and the marker generator draws only about 70 mA, even with standard TTL ICs. The 78L05 regulator should be available from the same companies that sell the TTL ICs used in this project.

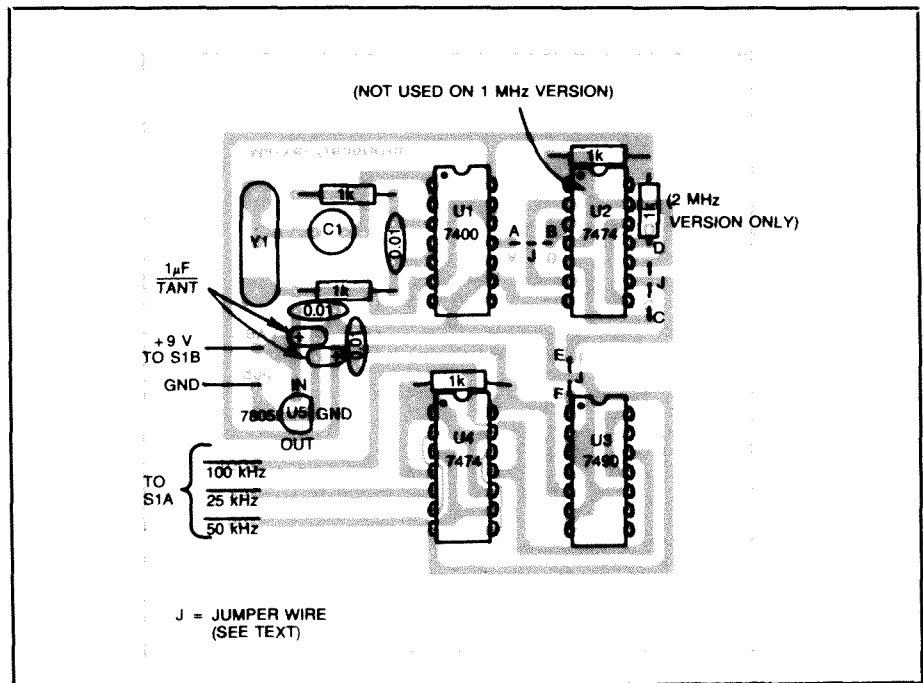

Fig. 66—Parts-placement diagram for the marker generator PC board. Consult Table 1 for information on placing the jumpers at points A, B, C, D, E and F. Extra pads in the oscillator section of the board allow for the use of a crystal in a small HC-25 holder or a larger HC-33 or HC-6 holder. Pads are also provided for different sizes of trimmer capacitor. A full-size etching pattern appears at the back of this book.

The input voltage to the regulator can be as high as 12-V dc; this may be desired if the marker generator is built inside a receiver using a 12-V power supply or some other source of 12-V dc is convenient. The low-power regulator may require a small press-on heat sink if 12-V dc is used, however.

A Radio Shack 2-pole 6-position rotary switch was used in this version of the marker generator, but any available rotary switch with at least four positions can be used. If a 2-pole switch is not available, a separate power switch can be used, but be careful to switch the generator off when it is not in use. An LED can be used as a power indicator.

Computer surplus crystals were used in all the units shown here, and all the generators could be trimmed to within 50 Hz of 100 kHz. These crystals are available from many of the electronics dealers listed in Chapter 35, such as BCD Electro or All Electronics Corporation. A crystal can also

be obtained from a manufacturer such as International Crystal or JAN Crystals, but the cost will be higher.

The value of C1 (the oscillator frequency trimmer) is not critical. Trimmers are available at Radio Shack in a 5 to 60 pF range—this is fine. Too small a value may not trim the oscillator frequency properly, and too large a value may prevent the oscillator from operating.

#### Adjustment and Calibration

To check the power supply section of the marker generator, measure the input and output voltages at U5. Input to the IC should be at least 8 V, and the output should be between 4.8 and 5.2 V.

Use an oscilloscope to observe the output waveform as S1 is rotated to select the 100, 50 and 25-kHz marker signals. The output should approximate a 3 to 5 V peak-to-peak square wave. The larger the value of the coupling capacitor C2, the less

“square” the output will be as the higher-frequency harmonics are attenuated.

The easiest way to calibrate the marker generator is with a frequency counter. With the counter connected to the output of the calibrator, adjust C1 until the counter measures the frequency to the desired precision. Greater capacitance at C1 will lower the oscillator frequency; if the oscillator will not trim with C1 at maximum capacitance, a low-value capacitor can be added in parallel with C1 to further reduce the oscillator frequency.

If a frequency counter is not available, the generator can be calibrated using WWV. Tune in WWV and disconnect the receiver antenna. Switch the receiver to the CW position (or turn on the BFO) without changing the setting of the tuning dial. Connect a short piece of wire to the output of the generator and place it near the receiver. Adjust C1 until the marker generator can be clearly heard in the receiver.

## Chapter 35

# Component Data

### INDEX OF TABLES IN CHAPTER 35

Table Number	Title	Page Number	Table Number	Title	Page Number
1	Resistor-Capacitor Color Code	35-1	22	Low-Noise Transistors	35-16
2	Standard Values for Capacitors and Resistors	35-2	23	RF Power Transistors, High Frequency, Low Voltage Amplifier Transistors, Power FETs	35-16&17
3	EIA Temperature Characteristic Code for Disc-Ceramic Capacitors	35-3	24	VHF and UHF Class-A Linear Transistors	35-18
4	EIA Designations for Capacitor Temperature Coefficient	35-3	25	Suggested Small-Signal FETs	35-18
5	EIA Capacitance Tolerance Codes	35-3	26	Power FETs	35-19
6	Approximate Series-Resonant Frequencies of Disc-Ceramic Bypass Capacitors	35-4	27	General Purpose Silicon Power Transistors	35-20&21
7	Powdered-Iron Toroid Cores—Magnetic Properties	35-4	28	Package Information	35-22
8	Powdered-Iron Toroid Cores—Dimensions	35-4	29	Integrated Circuit Operational Amplifiers	35-23
9	Color Code for Hookup Wire	35-5	30	IC Op Amp Base Diagrams	35-24&25
10	Ferrite Toroid Cores—Properties	35-5	31	Three-Terminal Voltage Regulators	35-26&27
11	Copper-Wire Table	35-6	32	Coaxial Cable End Connectors	35-28&29
12	EIA Vacuum-Tube Base Diagrams	35-7	33	Cross-Family Adapters	35-29
13	Triode Transmitting Tubes	35-8	34	Miniature Lamp Guide	35-30&31
14	Tetrode and Pentode Transmitting Tubes	35-9&10	35	Crystal Holders	35-32
15	TV Deflection Tubes	35-11	36	Properties of Common Thermoplastics	35-33—35
16	Semiconductor Diode Specifications	35-11	37	TTL Families	35-35
17	Voltage-Variable Capacitance Diodes	35-12	38	Fractions of an inch with Metric Equivalents	35-36
18	Zener Diodes	35-12—14	39	Aluminum Numbers for Amateur Use	35-36
19	Metal-Oxide Varistors Transient Suppressors	35-15	40	Voltage-to-Power Conversion Table	35-37
20	Japanese Semiconductor Nomenclature	35-15	41	Equivalent Values of Reflection Coefficient, Attenuation, SWR and Return Loss	35-38
21	General-Purpose Transistors	35-15	42	ARRL Parts Suppliers List	35-38&39

Few of us have the time or space to collect all the literature available on the many different commercially manufactured components. Even if we did, the task of keeping track of new and obsolete devices would surely be formidable. Fortunately, amateurs tend to use a limited number of component types. This chapter provides a source of information on the kinds of components most often encountered by the amateur experimenter.

#### Component Values

Values of composition resistors and small capacitors (mica and ceramic) are specified throughout this *Handbook* in terms of "preferred values." In the preferred-number system, all values represent (approximately) a constant-percentage increase over the next lower value. The base of the system is the number 10. Only two significant figures are used.

"Tolerance" means that a variation of plus or minus the percentage given is considered satisfactory. For example, the actual resistance of a "4700-ohm" 20-percent resistor can lie anywhere between 3700 and 5600 ohms, approximately. The permissible variation in the same resistance value with 5-percent tolerance would be in the range from 4500 to 4900 ohms, approximately.

In the component specifications in this *Handbook*, it is to be understood that when no tolerance is specified the *largest* tolerance available in that value will be satisfactory.

**Table 1**  
**Resistor-Capacitor Color Code**

Color	Significant Figure	Decimal Multiplier	Tolerance (%)	Voltage Rating*
Black	0	1	—	—
Brown	1	10	1*	100
Red	2	100	2*	200
Orange	3	1,000	3*	300
Yellow	4	10,000	4*	400
Green	5	100,000	5*	500
Blue	6	1,000,000	6*	600
Violet	7	10,000,000	7*	700
Gray	8	100,000,000	8*	800
White	9	1,000,000,000	9*	900
Gold	—	0.1	5	1000
Silver	—	0.01	10	2000
No color	—	—	20	500

\*Applies to capacitors only.

Values that do not easily fit into the preferred-number system (such as 500, 25,000) can be substituted. It is obvious, for example, that a 5000-ohm resistor falls well within the tolerance range of the 4700-ohm 20-percent resistor used in the example above. It would not, however, be usable if the tolerance were specified as 5 percent.

#### Component Markings

The values of small components such as capacitors and resistors are usually marked with standard color codes or cryptic abbreviations. If you have an ohmmeter and capacitor meter, you can quickly determine the value of an unknown component. If not, the information in the following

section can help you identify the majority of components you're likely to encounter.

Table 1 shows the standard resistor-capacitor color code. From the information in Table 1, you can determine the value and tolerance of most resistors. You can also use this information to determine the value, tolerance and voltage rating of some capacitors, such as mica and molded paper types.

Table 2 shows standard values for resistors and capacitors. Note that these are the significant figures in the value and that these standard values may be multiplied by powers of 10. For example, 2.2  $\mu$ F, 22  $\mu$ F, 220  $\mu$ F and 2200  $\mu$ F are all standard capacitance values. Standard resistor values

**Table 2**

**Standard Values for Capacitors and Resistors**

*1.0	*1.5	*2.2	*3.3	*4.7	*6.8
1.1	1.6	2.4	3.6	5.1	7.5
*1.2	*1.8	*2.7	*3.9	*5.6	*8.2
1.3	2.0	3.0	4.3	6.2	9.1

Note: All values available in  $\pm 5\%$   
 \*Available in  $\pm 10\%$

include 1.5  $\Omega$ , 15  $\Omega$ , 150  $\Omega$ , 1.5 k $\Omega$ , 15 k $\Omega$ , 150 k $\Omega$ , 1.5 M $\Omega$  and 15 M $\Omega$ .

**Capacitor Markings**

The value, tolerance, temperature characteristics and voltage rating of many small capacitors such as disc-ceramic, mica and tantalum types can be determined from a color code or from a combination of letters and numbers. Fig. 1 shows several popular marking systems.

In addition to the value, disc-ceramic capacitors may be marked with a letter/number combination signifying temperature characteristics. See Table 3. For example, a capacitor marked Z5U is suitable for use between  $+10$  and  $+85^\circ\text{C}$ , with a maximum capacitance change of  $-56\%$  or  $+22\%$ .

Capacitors with highly predictable temperature coefficients of capacitance are sometimes used in oscillators that must be frequency stable with temperature. If an application called for a temperature coefficient of  $-750$  parts per million per degree Celsius (N750), a capacitor marked U2J would be suitable. These codes are listed in Table 4.

Some capacitors, such as dipped silver mica units, have a letter designating the capacitance tolerance. These letters are deciphered in Table 5.

**Fixed-Value Resistors**

Composition resistors (and small wire-wound units molded in cases identical to the composition type) are color-coded as shown in Fig. 2. Color bands are used on resistors having axial leads; on radial-lead resistors the colors are placed as shown in the drawing. When bands are used for color coding the body color has no significance.

Examples: A resistor of the type shown in the lower drawing of Fig. 2 has the fol-

Fig. 1 — Capacitors can be identified by color codes and markings. Shown here are identifying markings found on many common capacitor types.

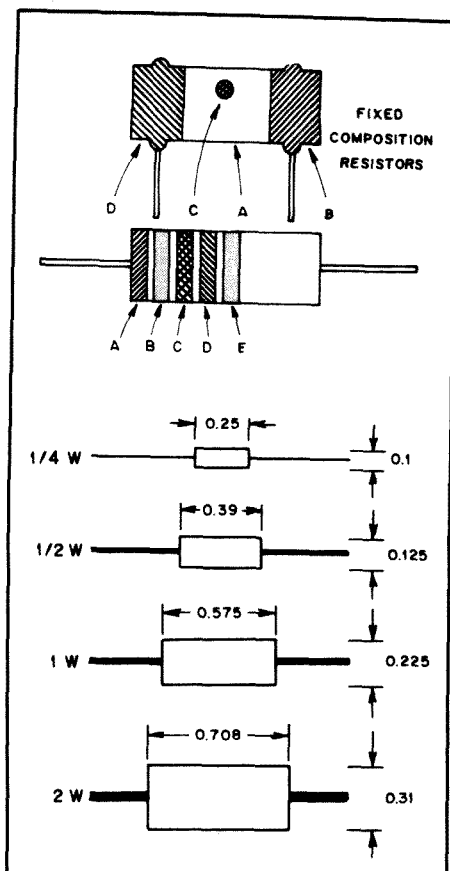

Fig. 2 — Color coding and body size for fixed resistors. The color code is given in Table 1. The colored areas have the following significance.

- A — First significant figure of resistance in ohms.
- B — Second significant figure.
- C — Decimal multiplier.
- D — Resistance tolerance in percent. If no color is shown the tolerance is  $\pm 20\%$ .
- E — Relative percent change in value per 1000 hours of operation; Brown, 1%; Red, 0.1%; Orange, 0.01%; Yellow, 0.001%.

lowing color bands: A, red; B, red; C, orange; D, no color. The significant figures are 2,2 (22) and the decimal multiplier is 1000. The value of resistance is therefore 22,000 ohms and the tolerance is  $\pm 20$  percent.

A resistor of the type shown in the upper drawing of Fig. 2 has the following colors: Body (A), blue; end (B), gray; dot, red; end (D), gold. The significant figures are 6, 8 (68) and the decimal multiplier is 100, so the resistance is 6800 ohms. The tolerance is  $\pm 5$  percent.

The preferred values over one decade are given in Table 2. All resistance values (from less than 1 ohm to about 22 megohms) are available in  $\pm 2\%$  metal film and  $\pm 5\%$  carbon-composition units.

Carbon composition and metal film resistors have standard power ratings of 1/10, 1/8, 1/4, 1/2, 1 and 2 watts. The 1/10- and 1/8-watt sizes are expensive and difficult to purchase in small quantity.

Table 3

### EIA Temperature Characteristic Code for Disc Ceramic Capacitors

Minimum Temperature	Maximum Temperature	Max. Cap. Change Over Temp. Range
X $-55^{\circ}\text{C}$	2 $+45^{\circ}\text{C}$	A $\pm 1.0\%$
Y $-30^{\circ}\text{C}$	4 $+65^{\circ}\text{C}$	B $\pm 1.5\%$
Z $+10^{\circ}\text{C}$	5 $+85^{\circ}\text{C}$	C $\pm 2.2\%$
	6 $+105^{\circ}\text{C}$	D $\pm 3.3\%$
	7 $+125^{\circ}\text{C}$	E $\pm 4.7\%$
		F $\pm 7.5\%$
		P $\pm 10\%$
		R $\pm 15\%$
		S $\pm 22\%$
		T $-33\%, +22\%$
		U $-56\%, +22\%$
		V $-82\%, +22\%$

Table 4

### EIA Designations for Capacitor Temperature Coefficient

Industry	EIA
NP0	C0G
N033	S1G
N075	U1G
N150	P2G
N220	R2G
N330	S2H
N470	T2H
N750	U2J
N1500	P3K
N2200	R3L

Table 5

### EIA Capacitance Tolerance Codes

C	$\pm \frac{1}{4}$ pF
D	$\pm \frac{1}{2}$ pF
F	$\pm 1$ pF or $\pm 1\%$
G	$\pm 2$ pF or $\pm 2\%$
J	$\pm 5\%$
K	$\pm 10\%$
L	$\pm 15\%$
M	$\pm 20\%$
N	$\pm 30\%$
P	$-0\%, +100\%$ or GMV
W	$-20\%, +40\%$
Y	$-20\%, +50\%$
Z	$-20\%, +80\%$

They are used only where miniaturization is essential. The 1/4-, 1/2-, 1- and 2-watt composition resistors are drawn to scale in Fig. 2. Metal film resistors are usually slightly smaller than carbon units of the same power rating. Film resistors can often be distinguished by a glossy vitreous enamel coating and an hourglass profile as opposed to a right circular cylinder. They are the most commonly available type today, but the resistive film is often deposited in the form of a solenoid. Thus, they can be highly inductive and therefore less desirable than carbon-composition resistors in RF circuits.

### Power Transformers

- 1) Primary Leads: black
  - If tapped:
    - Common: black
    - Tap: black and yellow striped
    - Finish: black and red striped
- 2) High-Voltage Plate Winding: red
  - Center-Tap: red and yellow striped
- 3) Rectifier Filament Winding: yellow
  - Center-Tap: yellow and blue striped
- 4) Filament Winding no. 1: green
  - Center-Tap: green and yellow striped
- 5) Filament Winding no. 2: brown

- Center-Tap: brown and yellow striped
- 6) Filament Winding no. 3: slate
  - Center-Tap: slate and yellow striped

### IF Transformers

- Plate lead — blue
- B-plus lead — red
- Grid (or diode) lead — green
- Grid (or diode) return — black

Note: If the secondary of the IF transformer is center-tapped, the second diode plate lead is green-and-black striped, and black is used for the center-tap lead.

### Audio Transformers

- Plate (finish) lead of primary — blue
- B-plus lead (this applies whether the primary is plain or center-tapped) — red
- Plate (start) lead on center-tapped primaries. (Blue may be used for this lead if polarity is not important) — brown
- Grid (finish) lead to secondary — green
- Grid return (this applies whether the secondary is plain or center-tapped) — black
- Grid (start) lead on center-tapped secondaries (Green may be used for this lead if polarity is not important) — yellow

Note: These markings apply also to line-to-grid and tube-to-line transformers.

Fig. 3 — Color coding for tubular encapsulated RF chokes. At A, an example of the coding for an 8.2-μH choke is given. At B, the color bands for a 330-μH inductor are illustrated. The color code is given in Table 1.

Fig. 4 — Color coding for semiconductor diodes. At A, the cathode is identified by the double-width first band. At B, the bands are grouped toward the cathode. Two-figure designations are signified by a black first band. The color code is given in Table 1. The suffix-letter code is: A — brown, B — red, C — orange, D — yellow, E — green, F — blue. The 1N prefix is understood.

Table 9

## Color Code for Hookup Wire

Wire Color	Type of Circuit
Black	Grounds, grounded elements and returns
Brown	Heaters or filaments, off ground
Red	Power supply B plus
Orange	Screen grids and base 2 of transistors
Yellow	Cathodes and transistor emitters
Green	Control grids, diode plates, and base 1 of transistors
Blue	Plates and transistor collectors
Violet	Power supply, minus leads
Gray	Ac power line leads
White	Bias supply, B or C minus, AGC

Note: Wires with tracers are coded in the same manner as solid-color wires, allowing additional circuit identification over solid-color wiring. The body of the wire is white and the color band spirals around the wire lead. When more than one color band is used, the widest band represents the first color.

## Digital ICs

Digital-logic ICs are divided into two basic families, bipolar and MOS, depending on the transistor types used. These families are further divided into sub-families by the internal circuitry of the IC ("totem pole" output versus open collector output) or by differences in fabrication techniques (silicon gate-recessed oxide versus metal gate). The digital ICs most commonly encountered by amateurs are the TTL (bipolar) and CMOS (MOS) types.

The TTL family is divided as shown in tables presented later in this chapter. It is important to recognize the differences between the types of TTL ICs. In many digital circuits, ICs of several types are connected together. If care is not exercised when doing this, one or more of the TTL outputs may be overloaded. Be aware that the different series of TTL operate at different speeds and with different propagation delays (see Chapter 8).

To determine if a substitute TTL IC can be used in a given circuit, several questions must be answered. First, is the logic element operating at a speed below the maximum specified for the TTL type? Will any output of the IC be required to sink or source a current beyond its capabilities? Even if the answers to these questions seem to indicate that the IC can be used, a deeper analysis of the circuit may reveal that a change in propagation delay will affect the operation of the circuit. If in doubt the IC can always be tried in the circuit. TTL ICs of the "wrong" type will generally not harm anything.

The major consideration when using CMOS is operating speed. CMOS logic is inherently slow. If clock rates greater than a few megahertz are required, CMOS probably cannot be used (although higher speed CMOS families have recently been introduced by several manufacturers). The CMOS speed question is complicated by the fact that the speed of any CMOS logic element is affected by its operating voltage. A manufacturer's data book should be consulted to determine the speed of a specific IC.

## Finding Parts

No chapter on components and component data would be complete without information on where to buy. Amateurs, on a dwarfed scale, must function as purchasing agents in these perplexing times. A properly equipped buyer maintains as com-

plete a catalog file as possible. Many of the companies listed in the last table in this chapter will provide free catalogs upon written request. Others may charge a small fee for catalogs. Mail ordering, especially for those distant from metropolitan areas, is today's means to the desired end when collecting component parts for an amateur project. Prices are, to some extent, competitive. A wise buyer will study the catalogs and select his merchandise accordingly.

Delays in shipment can be lessened by avoiding the use of personal checks when ordering, especially for those distant from metropolitan areas. Personal checks often take a week to clear, thereby causing frustrating delays in the order reaching you. The parts suppliers table is updated with each new edition of this *Handbook*. Suppliers wishing to be listed in the table are urged to contact the editors.

<sup>1</sup>A mil is 0.001 inch. A circular mil is a square mil  $\times \pi/4$ . The circular mil (c.m.) area of a wire is the square of the mil diameter.

<sup>2</sup>Figures given are approximate only; insulation thickness varies with manufacturer.

<sup>3</sup>Max. wire temp. of 212° F (100° C) and max. ambient temp. of 135° F (57° C).

<sup>4</sup>700 circular mils per ampere is a satisfactory design figure for small transformers, but values from 500 to 1000 c.m. are commonly used.

**Table 12**  
**EIA Vacuum-Tube Base Diagrams**

Socket connections correspond to the base designations given in the column headed "Base" in the classified tube-data tables. Bottom views are shown throughout. Terminal designations are as follows:

A — Anode	B — Deflecting Plate	IS — Internal Shield	RC — Ray-Control Electrode
BP — Bayonet Pin	F — Filament	K — Cathode	Ref — Reflector
BS — Base Sleeve	FE — Focus Elect.	NC — No Connection	S — Shell
C — Ext. Coating	G — Grid	P — Plate (Anode)	TA — Target
CL — Collector	H — Heater	P <sub>1</sub> — Starter-Anode	U — Unit
	IC — Internal Con.	P <sub>BF</sub> — Beam Plates	● — Gas-Type Tube

Alphabetical subscripts D, P, T and HX indicate, respectively, diode unit, pentode unit, triode unit or hexode unit in multi-unit types. Subscript CT indicates filament or heater tap.

Generally when the No. 1 pin of a metal-type tube, with the exception of all triodes, is shown connected to the shell, the No. 1 pin in the glass (G or GT) equivalent is connected to an internal shield.

\*On 12AQ, 12AS and 12CT: index = large lug; ● = pin cut off

 AB<sub>2</sub>-GG = Grounded-grid class AB<sub>2</sub> amp.  
 B-GG = Grounded-grid class B amp. (single tone)  
 GG-O = Grounded-grid osc.  
 GIC = Grid-isolation circuit.

GMA = Grid-modulated amp.

2 Values are for two tubes in push-pull.

3 Max. signal value.

4 Peak AF grid-to-grid volts.

5 Max. cathode current in mA.

6 Forced-air cooling required.

7 Key-down CW.

Table 14 — Tetrode and Pentode Transmitting Tubes

Listed in order of plate dissipation

Type	Maximum Ratings					Cathode			Capacitances			Base	Typical Operation

## Japanese Semiconductor Nomenclature

All transistors manufactured in Japan are registered with the Electronic Industries Association of Japan (EIAJ). In addition, the Japan Industrial Standard JIS-C-7012 provides type numbers for transistors and thyristors.

Each transistor type number consists of five elements.

Example:

i      ii      iii      iv      v  
 $\frac{1}{2}$     S      C      82D    A  
 Figure Letter Letter Figure Letter

- i) Kind of device, indicating the number of effective electrical connections minus one.  
 ii) For a semiconductor registered with the EIAJ, this letter is always an S.  
 iii) This letter designates polarity and application, as follows:

## Letter Polarity and Application

- A PNP transistor, high frequency  
 B PNP transistor, low frequency  
 C NPN transistor, high frequency  
 D NPN transistor, low frequency  
 E P-gate thyristor  
 G N-gate thyristor  
 H N-base unijunction transistor  
 J P-channel FET  
 K N-channel FET  
 M Bi-directional triode thyristor

- iv) These figures designate the order of application for EIAJ registration, starting with 11.  
 v) This letter indicates the level of improvement. An improved device may be used in place of a previous-generation device, but not necessarily the other way around.

Table 24

## VHF and UHF Class-A Transistors

The devices listed below are excellent for class-A linear applications.  
The devices are listed according to increasing current-gain bandwidth ( $f_T$ ).

Device Type	Nominal Test Conditions $V_{CE}/I_C$ Volts/mA	$f_T$ MHz Min.	Noise Figure Max/Freq. MHz	Distortion Specifications			Package
				2nd Order IMD	3rd Order IMD	Output Level dBmV	
MRF501	6/5	600	4.5*/200				TO-72
MRF502	6/5	800	4.0*/200				TO-72
2N5179	6/5	900	4.5/200				TO-72
BFY90	5/2	1000	5.0/500				TO-72
BFW92	5/2	1000	4.0/500				302A-01
2N6305	5/10	1200	5.5/450				TO-72
BFX89	5/25	1200	6.5/500				TO-72
2N5109	15/50	1200	3.0*/200				TO-39
2N5943	15/50	1200	3.4/200	-50		+50	TO-39
2N6304	5/10	1400	4.5/450				TO-72
MRF511	20/80	1500	7.3*/200	-50	-65	+50	144D-04

**Table 31****Three-Terminal Voltage Regulators****Listed numerically by device**

Device	Description	Package	Voltage	Current (Amps)
317	Adj Pos	TO-205	+1.2 to +37	0.5
317	Adj Pos	TO-204, TO-220	+1.2 to +37	1.5
317L	Low Current Adj Pos	TO-205, TO-92	+1.2 to +37	0.1
317M	Med Current Adj Pos	TO-220	+1.2 to +37	0.5
350	High Current Adj Pos	TO-204, TO-220	+1.2 to +33	3.0
337	Adj Neg	TO-205	-1.2 to -37	0.5
337	Adj Neg	TO-204, TO-220	-1.2 to -37	1.5
337M	Med Current Adj Neg	TO-220	-1.2 to -37	0.5
309		TO-205	+5	0.2
309		TO-204	+5	1.0
323		TO-204, TO-220	+5	3.0
140-XX	Fixed Pos	TO-204, TO-220	Note 1	1.0
340-XX		TO-204, TO-220		1.0
78XX		TO-204, TO-220		1.0
78LXX		TO-205, TO-92		0.1
78MXX		TO-220		0.5
78TXX		TO-204		3.0
79XX	Fixed Neg	TO-204, TO-220	Note 1	1.0
79LXX		TO-205, TO-92		0.1
79MXX		TO-220		0.5

Note 1—XX indicates the regulated voltage; this value may be anywhere from 1.2 volts to 35 volts. A 7815 is a positive 15-volt regulator, and a 7924 is a negative 24-volt regulator.

The regulator package may be denoted by an additional suffix, according to the following:

Package	Suffix
TO-204 (TO-3)	K
TO-220	T
TO-205 (TO-39)	H, G
TO-92	P, Z

For example, a 7812K is a positive 12-volt regulator in a TO-204 package. An LM340T-5 is a positive 5-volt regulator in a TO-220 package. In addition, different manufacturers use different prefixes. An LM7805 is equivalent to a  $\mu$ A 7805 or MC7805.

NOTES: Z = 50  $\Omega$  Freq. range: 0.4 GHz w/low reflection; usable to 11 GHz.  
 Voltage rating: 500 V p-p. Dielectric withstanding voltage 500 V<sub>RMS</sub>.  
 SWR: 1.3 max 0.4 GHz. RF leakage -55 dB min @ 3 GHz  
 Insertion loss: 0.2 dB max @ 3 GHz.  
 Temp. limits: TFE: -67° to 390°F (-55° to 199°C)  
 Rexolite insulators: -67° to 185°F (-55° to 85°C)

W-Wire terminals. (—)Not illustrated. (+)-Wedge base. L-Long life.

## BULB STYLES

\*\*Bulbs are described by a letter indicating shape and a number that is an approximation of diameter expressed in eighths of an inch. For example S-8 is "S" shape, 8 eighths or 1 inch in dia.

(T) W-Wire terminals. (\*) Knurled screw.

<sup>a</sup>Test specimen molding conditions, 275°F mold temperature.<sup>b</sup>Representative of a series of various pigmented compounds.

**Table 36 (continued)**

**Polyvinyl Chloride (PVC)**

**Advantages:**

- can be compounded with plasticizers, fillers, stabilizers, lubricants and impact modifiers to product wide range of physical properties.
- can be pigmented to almost any color
- Rigid PVC has good corrosion and stain resistance, thermal & electrical insulation, and weatherability

**Disadvantages:**

- base resin can be attacked by aromatic solvents, ketones, aldehydes, naphthalenes, and some chloride, acetate, and acrylate esters
- should not be used above 140° F

**Applications:**

- conduit
- conduit boxes
- electrical fittings
- housings
- pipe
- wire and cable insulation

**Polystyrene**

**Advantages:**

- low cost
- moderate strength
- electrical properties only slightly affected by temperature and humidity
- sparkling clarity
- impact strength is increased by blending with rubbers, such as polybutadiene

**Disadvantages:**

- brittle
- low heat resistance

**Applications:**

- capacitors
- light shields
- knobs

**Polypheylene Sulfide (PPS)**

**Advantages:**

- excellent dimensional stability
- strong
- high-temperature stability
- chemical resistant
- Inherently completely flame retardant
- completely transparent to microwave radiation.

**Applications:**

- R3-R5 have various glass-fiber levels that are suitable for applications demanding high mechanical and impact strength as well as good dielectric properties.
- R8 and R10 are suitable for high arc-resistance applications
- R9-901 is suitable for encapsulation of electronic devices

**Polypropylene**

**Advantages:**

- low density
- good balance of thermal, chemical, and electrical properties
- moderate strength (increases significantly with glass-fiber reinforcement)

**Disadvantages:**

- Electrical properties affected to varying degrees by temperature (as temperature goes up, dielectric strength increases and volume resistivity decreases.)
- Inherently unstable in presence of oxidative and UV radiation

**Applications:**

- Automotive battery cases
- blower housings
- fan blades
- fuse housings
- insulators
- lamp housings
- supports for current-carrying electrical components.
- TV yokes

**Polyethylene (PE)**

**Advantages: Low Density PE**

- Good toughness
- excellent chemical resistance
- excellent electrical properties
- low coefficient of friction
- near-zero moisture absorption
- easy to process
- relatively low heat resistance

**Disadvantage**

- susceptible to environmental and some chemical stress cracking
- wetting agents (such as detergents) accelerate stress cracking

**Advantages: High Density PE**

- Same as above, plus increased rigidity and tensile strength

**Advantages: Ultra-High Molecular Weight PE**

- outstanding abrasion resistance
- low coefficient of friction
- high impact strength
- excellent chemical resistance
- material does not break in impact strength tests using standard notched specimens

**Applications:**

- bearings
- components requiring maximum abrasion resistance, impact strength, and low coefficient of friction

**Phenolic**

**Advantages:**

- low cost
- superior heat resistance
- high heat-deflection temperatures
- good electrical properties
- good flame resistance
- excellent moldability
- excellent dimensional stability
- good water and chemical resistance

**Applications:**

- commutators and housings for small motors
- heavy duty electrical components
- rotary-switch wafers
- insulating spacers

**Nylon**

**Advantages**

- excellent fatigue resistance
- low coefficient of friction
- toughness a function of degree of crystallinity
- resists many fuels and chemicals
- good creep- and cold-flow resistance as compared to less rigid thermoplastics
- resists repeated impacts

**Disadvantages:**

- all nylons absorb moisture
- nylons that have not been compounded with a UV stabilizer are sensitive to UV light, and thus not suitable for extended outdoor use

**Applications**

- bearings
- housing and tubing
- rope
- wire coatings
- wire connectors
- wear plates

**Table 37**

**TTL Families**

Listed by ascending maximum clock frequency.

TTL Series	Input Pull-up Resistor (kΩ)	Maximum High-level Input Current (μA)	Maximum Low-level Input Current (mA)	Typical Gate Propagation Delay Time (ns)	Maximum Flip-flop Clock Frequency (MHz)

**Table 39****Aluminum Numbers for Amateur Use**

<i>Common Alloy Numbers</i>	
<i>Type</i>	<i>Characteristic</i>
2024	Good formability, high strength
5052	Excellent surface finish, excellent corrosion resistance, normally not heat treatable for high strength
6061	Good machinability, good weldability, can be brittle at high temps
7075	Good formability, high strength
<i>Common Tempers</i>	
<i>Type</i>	<i>Characteristics</i>
T0	Special soft condition
T3	Hard
T6	Very hard, possibly brittle
TXXX	Three digit tempers — usually specialized high-strength heat treatments, similar to T6
<i>General Uses</i>	
<i>Type</i>	<i>Uses</i>
2024-T3	Chassis boxes, antennas, anything that will be bent or flexed repeatedly
7075-T3	
6061-T6	Mounting plates, welded assemblies or machined parts

Table 40

## Voltage-Power Conversion Table

Based on a 50-ohm system

Voltage			Power	
RMS	Peak-to-Peak	dBmV	Watts	dBm
0.01 $\mu$ V	0.0283 $\mu$ V	-100	$2 \times 10^{-18}$	-147.0
0.02 $\mu$ V	0.0566 $\mu$ V	-93.98	$8 \times 10^{-18}$	-141.0

To the best of our knowledge the suppliers shown are willing to sell components to amateurs in small quantities by mail. This listing does not necessarily indicate that these firms have the approval of ARRL.

# How to Become a Radio Amateur

**W**hy become a ham? Perhaps because you want to participate in hands-on technical experiments. Perhaps you heard about ham radio from a television or magazine advertisement. Or maybe you witnessed Amateur Radio operators providing emergency communications during a recent disaster. Or it could be the desire to talk with people easily and freely, people who may live down the street or thousands of miles away.

Whatever your reason, it's not hard to become a radio amateur. This chapter will guide you along the path. Millions of people around the world have done it; youngsters too young to ride a bicycle have gotten their amateur licenses (the record is a five year old), as have people over 95.

In the United States, Amateur Radio operation is governed by the Federal Communications Commission (FCC). The FCC rules, known as Part 97 for the section dealing specifically with Amateur Radio, describe five levels of amateur license. These follow a ladder-like progression. Each license class has a more difficult examination, but also grants greater operating privileges. The *Novice* is the introductory license level. Other amateur licenses, in order of increasing privileges, are the Technician class, General class, Advanced class and Amateur Extra class.

The examination for the Novice license covers three main areas: First is some regulatory material, which is simply common sense (and therefore easy to learn). The second deals with on-the-air operating skills. And the third covers radio theory — purposely made easy and at an introductory level. In addition, you'll be tested on the Morse code. Aha!, you say, I knew there was a catch! It's not a catch. It's not even hard.

Learning the code is often regarded as the major obstacle to getting an amateur license. Not so! Realistically, it takes less than two weeks to learn the alphabet, 10

Amateur Radio — a hobby where *everyone* has fun. Here, Bill Christian, K4IKR (left), and Tim Dionne, KB4BDG, operate in the annual Field Day. During this two-day event, thousands of radio amateurs around the U.S. set up and operate portable emergency-powered stations.

numerals and punctuation; perhaps it will take you even less time, depending on your motivation. After you get the letters down, it's just a matter of regular practice until you're comfortably communicating at 5 words per minute (WPM). Higher speeds come easily, too! Again, the key is *regular*

practice. You could learn (and remember) seven Morse code letters in half an hour.

Novices can communicate *worldwide* using International Morse code, voice and digital modes such as RTTY and packet radio on a wide range of radio frequencies. The Novice license examination is free.

John Comella, N8AA, concentrates as he makes Morse code contacts.

Technician class licensees have Novice class privileges; they also are assigned additional frequencies in the very-high- and ultra-high-frequency (VHF and UHF) spectrums. The General class license permits even more frequency choices.

### A Close Look at the Novice Examination

As was briefly explained earlier, the Novice exam covers three main topics: Rules and Regulations, Operating Procedures and Amateur Radio Theory. Volunteer-examiner coordinators have put together a list of about 300 questions that cover these different areas. Every Novice exam is a randomly selected collection of 30 of these 300 questions. Each test is compiled as described in Table 1.

To show how a typical Novice exam might be worded, we'll go over a sample test. The answers are given as short phrases.

#### Rules and Regulations

*Q. What is a control operator?* A: A control operator is a licensed operator designated to be responsible for the emissions of a particular station.

*Q. What are the Novice class operator transmitting frequency privileges in the 80-meter band?* A: 3700-3750 kHz.

*Q. What does the term A1A emission mean?* A: CW Morse code without any audio modulation of the carrier.

*Q. Under what circumstances, if any, may the control operator cause false or*

**Table 1**  
**The Novice Class Written Examination**

Rules and Regulations:	9 questions
Operating Procedures:	2 questions
Radio Wave Propagation:	2 questions
Amateur Radio Practice:	4 questions
Electrical Principles:	4 questions
Circuit Components:	2 questions
Practical Circuits:	2 questions
Signals and Emissions:	2 questions
Antennas and Feedlines:	3 questions

*deceptive signals or communications to be transmitted?* A: Under no circumstances.

*Q. With which amateur stations may an FCC-licensed Amateur Radio station communicate?* A: All amateur stations, unless prohibited by the amateur's government.

*Q. An Amateur Radio station must be identified at least once every* A: 10 minutes.

*Q. Should an Amateur Radio operator receive an Official Notice of Violation from the FCC, how promptly should he/she respond?* A: Within 10 days.

The factual knowledge in this first section can be picked up easily by reading through the ARRL publication *Tune in the World With Ham Radio*.

#### Operating Procedures

*Q. The "T" in the RST signal report stands for* A: the tone of the signal.

#### Radio Wave Propagation

*Q. What type of propagation involves radio signals that travel along the ground?*

A: Ground-wave propagation.

#### Amateur Radio Practice

*Q. For safety purposes, how high should all portions of a horizontal wire antenna be?* A: High enough so that a person cannot touch them from the ground.

*Q. Why is harmonic radiation undesirable?* A: It will cause interference to other stations and/or result in out-of-band signal radiation.

*Q. A voltage standing wave ratio is measured with a(n)* A: SWR bridge.

#### Electrical Principles

*Q. What are the two polarities of a voltage?* A: Positive and negative.

*Q. Are audio frequencies higher or lower than radio frequencies?* A: Lower.

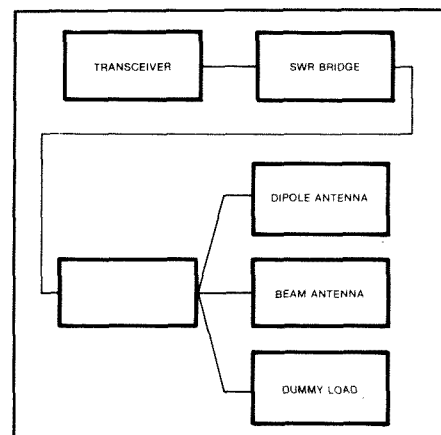

*Q. What is the unit of electrical current?* A: The ampere.

#### Circuit Components

*Q. What does a voltmeter measure?* A: Volts.

#### Practical Circuits

*Q. What is the unlabeled box in this block diagram?*

A. Antenna switch.

#### Signals and Emissions

*Q. What does the term "chirp" mean?* A: A slight shift in oscillator frequency each time a CW transmitter is keyed.

#### Antennas and Feedlines

*Q. When a vertical antenna is lengthened, what happens to its resonant frequency?*

A: It decreases.

*Q. What commonly available feedline can be buried directly in the ground for some distance without adverse affects?* A: Coaxial cable.

There is *nothing* hard about the Novice theory exam! If you want to see the rest of the 300 questions, a copy of the question

Listening to over-the-air practice transmissions is the best way to increase your speed and proficiency with the code. Members of the Mobile (Alabama) Amateur Radio Club put this philosophy to good use.

Study is more fun when you are part of a group. In an organized class you will find encouragement from your fellow students and help from a knowledgeable instructor.

pool is available free from ARRL Hq. Please include an s.a.s.e. with your request.

### Finding Help

You can choose several paths when going for your amateur license. There is the personalized-instruction route, the self-study route or the class method. No matter which one you choose, the ARRL can help you.

The ARRL has a program specifically set up to help people get their ham licenses, a referral service that ensures you get the help and assistance you need, and that you get it when you need it.

### Personalized Instruction

To get started toward your Amateur Radio license, write to ARRL Hq. in Newington, Connecticut. We will match you up with a Registered Amateur Radio Instructor in your area. There are thousands of Registered Instructors around the United States. Their level of instruction, names and addresses are kept in a computer file. The large number of Instructors ensures a wide geographical coverage. When you request assistance, there's a good chance you'll be linked with a Registered Instructor who lives close by.

The great benefit of the Registered Instructor system is that the Instructor offers patient instruction, tailored to the pace at which you feel comfortable. If you miss a point, your Instructor will spend as much time as is necessary to make sure you understand what's going on. This is the sort of education you can get only in the finest private schools.

Registered Instructors have altruistic reasons for helping you, the future ham. This buddy system works extremely well, and has been the path into the hobby for tens of thousands of radio amateurs. The personalized instruction and assistance provided by the Elmers, as Instructors are often called, can't be beat.

The Elmer is also the one who teaches you the Morse code, and often administers

the license examination, if you are preparing for the Novice license.

### Self Study

If you choose the self-study method, there's an excellent package that will guide you along the way. *Tune in the World With Ham Radio*, published by ARRL, will teach you all you need to know to pass your Novice examination. The book covers the concepts of amateur theory that are found in the Novice examination. It covers the following areas: Exploring ham radio; managing the radio spectrum (covering the regulatory and legal aspects of the hobby); learning the Morse code; understanding basic theory; setting up a Novice station; and a section on operating and operating activities. The package contains two Morse code tapes that teach you every letter, numeral and punctuation mark you need to know. The tapes build competence in the code with practice conversations.

### License Study Classes

The third alternative open to you as a prospective radio amateur is to attend license classes. These classes are usually sponsored by a local Amateur Radio club, and there are over 2000 such clubs all around the United States, usually centered in and around metropolitan areas.

Here again ARRL Hq. can help you. We have a listing of over 1700 *ARRL-Affiliated* clubs around North America. Many of these clubs run licensing classes twice a year, in the fall and spring, and register these classes with ARRL Hq. If you want to get in touch with a class in your area, give us a call. The club records are kept in a constantly accessible computer file, so we can rapidly give you the information you want.

A license class usually follows a 10-week schedule. Morse code is introduced simultaneously with the elementary theory needed for the Novice license. Class size commonly ranges from 5 to 50 people. You can take your license examination any time,

### You Can Do It Too!

Think Morse code is a difficult hurdle that takes weeks and weeks of hard work to master? Think again! Guy Mitchell, WD0DVX, of Buckingham, Iowa, picked up Morse code from tapes his parents were using for their Novice class. Soon, he began studying on his own, and mastered the alphabet and numbers with little difficulty. What makes this story unique is that Guy Mitchell was four years old when he passed the five-words-per-minute code test! He had had another birthday when he passed the written test, however. At five years of age, Guy was the youngest licensed ham radio operator in the U.S., and perhaps the world!

Guy Mitchell started kindergarten five months after he passed the Novice code test.

if you progress faster than the rest of the class.

If you want to get in touch with a radio amateur immediately, chances are that you'll find one right in your neighborhood. There is one ham for every 550 Americans, and a simple walk around your neighborhood might give good results: Look for houses or apartments with *large* antennas on the roof.

### The Code

Morse code should not be considered a

Susan Smith, K3YL, takes a break from handling a few Amateur Radio messages.

series of dots and dashes. Rather, words descriptive of the sound of the two different Morse code elements used: A dot is called a *dit*, and a dash is called a *dah*. The *dah*, the long tone, is three times as long as the *dit*.

When two or more dits are put together, or when a dit is followed immediately by a *dah*, as they are for 12 of the 26 letters and most of the numbers, they are written as *didit*, or *dididit* or *didah* (dropping the "t" from all but the final *dit*).

An easy method of learning the code, and one in which you'll learn seven letters in less than an hour, is the "EISH-TMO" system. This method works by teaching you letters by association and relation, a powerful learning tool, as teachers know.

Here is the EISH-TMO method:

E	<i>dit</i>	T	<i>dah</i>
I	<i>didit</i>	M	<i>dahdah</i>
S	<i>dididit</i>	O	<i>dahdahdah</i>
H	<i>didididit</i>		

You see how these first seven letters relate to one another. The rest of the Morse code letters are just about as easy to learn. Here's the next group:

A	<i>didah</i>	N	<i>dahdit</i>
W	<i>didahdah</i>	D	<i>dahdidit</i>
J	<i>didahdahdah</i>	B	<i>dahdididit</i>

From this point on, the relations become less apparent, but you've already learned half of the alphabet in a short time. Regular practice is the key to solidifying the code characters in your mind. After you get these few letters down, think about them as you go about your daily business. A good way to practice the code is to translate the letters you've learned whenever and wherever you see them — in newspapers, on signs, even as you dial the telephone.

Here are a few more letters.

U *didididit*  
 V *didididah* (think of Beethoven's fifth symphony)

G *dahdahdit*  
 Z *dahdahdidit*  
 K *dahdidah*  
 R *didahdit*  
 P *didahdahdit*  
 X *dahdididah*

These Chinese amateurs use directional antennas to search for a hidden transmitter during a "fox hunt."

Now come the letters with no relatives, the "oddballs."

F	<i>dididahdit</i>
C	<i>dahdidahdit</i>
L	<i>didahdidit</i>
Q	<i>dahdahdidah</i>
Y	<i>dahdidahdah</i>

And that's the entire alphabet. Not too hard, and a lot easier than learning how to touch type or practicing the piano. You can take it with you wherever you go, too!

When listening to code-practice transmissions, as you hear the tones, translate them in your head and write down the letters on paper. Eventually you'll be able to skip the paper, but that shouldn't be your immediate goal. At this stage, it's important to practice the letters you've learned as often as possible. After learning how to receive and translate code in your head, you should practice sending it. The key is to first train the ear, then train the hand.

You also have to know the numerals from zero to nine for the Novice code examination. Each numeral consists of five code elements. You'll see how straightforward this is:

One	<i>didahdahdahdah</i>
Two	<i>dididahdahdah</i>
Three	<i>didididahdah</i>
Four	<i>dididididah</i>
Five	<i>dididididit</i>

You probably noticed the pattern followed by these first five digits. Six through zero follow a similar pattern.

Six	<i>dahdidididit</i>
Seven	<i>dahdahdididit</i>
Eight	<i>dahdahdahdidit</i>
Nine	<i>dahdahdahdahdit</i>
Zero	<i>dahdahdahdahdah</i>

You must learn three punctuation marks

With today's miniaturized, transistorized transceivers (a transmitter and receiver in one package), an Amateur Radio station can be set up just about anywhere. WD8KCP can talk around the world from the kitchen.

for the Novice code test. These are: The *period* (*didahdidahdidah*), the *comma* (*dahdahdididahdah*) and the *question mark* (*dididahdahdidit*). The rhythm of punctuation marks makes them easy to learn.

Computer-aided Morse code instruction may be of interest to you. Programs that teach the Morse code are available for most popular home computers.

### The Handi-Ham System

People with disabilities will find the world of Amateur Radio easy to enter, and for individuals restricted to the confines of a bed and four walls, Amateur Radio can be a vehicle for communication, fraternity and fellowship with other human beings in the outside world. A valuable therapeutic tool, Amateur Radio continues to hold a profound appeal for individuals with physical handicaps. It is a means of people-to-people contact on a basis of absolute equality — two minds communicating and relating on a level of mutual and equal empathy.

Amateur Radio is person-to-person communication, spanning miles and continents.

Amateur Radio is a hobby for young and old alike. From left to right, Brad Stave (KA0BJJ), Steve Stave (KA0AEK), and Art Stevens (K0LXI), ages 12, 11 and 88, respectively, operate K0LXI.

A special-interest organization is set up for radio amateurs with disabilities. Called the Courage HANDI-HAM system, this group is an international service organization of over 2000 handicapped and able-bodied radio amateurs working together to bring ham radio to individuals with physical handicaps. There are HANDI-HAM members in every state and in 20 other countries ready to help. They can provide textbooks (or cassette recordings thereof), code practice tapes, a key and a code practice oscillator. There are local HANDI-HAMS to assist you with studies at home. Once you receive your license, the Courage HANDI-HAM system may lend you basic ham radio equipment to get you started on the air.

For information, contact the Courage Center at 3915 Golden Valley Rd., Golden Valley, MN 55422, tel. 612-588-0811.

### Putting It All Together

Assembling a station doesn't have to be expensive. Many companies that sell used equipment advertise in *QST*. First you'll need a receiver. That receiver will do three things for you. By listening to over-the-air code-practice transmissions, you can increase your skill with the code. By monitoring the ham bands you will get an idea of what happens; you'll increase your familiarity with ham radio operation. And after you get your license, you can use the receiver for making contacts. For these reasons, buy the best receiver you can afford. Think of the long-term use of the equipment. The extra dollar spent shrinks as you use the gear year after year.

Of course, you don't have to buy a receiver. You can build your own. This *Handbook* has receiver designs in Chapter 30.

### W1AW Code Practice

Code practice is sent by the ARRL Hq.

The W1FYM group uses a microcomputer to ensure they work stations only once per band. In keeping with the emergency and portable emphasis of Field Day, everything in this two-transmitter station is powered from the batteries at the bottom of the picture.

**Table 2**  
**W1AW Slow Code Practice Schedule**

10 P.M.	9 P.M.	8 P.M.	7 P.M.	T Th S Sn

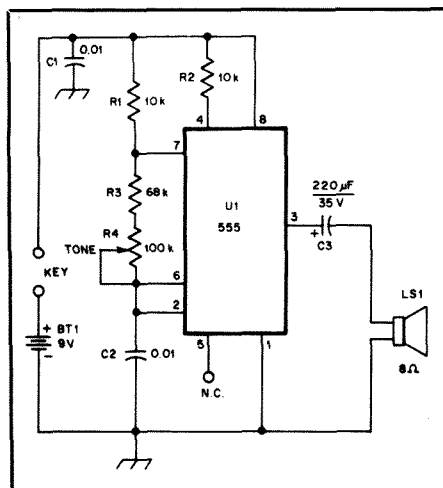

Fig. 1 — Schematic diagram of the code-practice oscillator. Radio Shack part numbers are given in parentheses.

BT1 — 9-V battery (23-553).

C1, C2 — 0.01- $\mu$ F capacitor (272-131).

C3 — 220- $\mu$ F, 35-V electrolytic capacitor (272-1029).

LS1 — 2-in loudspeaker, 8  $\Omega$  (40-245).

R1, R2 — 10-k $\Omega$  resistor, 1/4 W (271-1335).

R3 — 68-k $\Omega$  resistor, 1/4 W.

R4 — 100-k $\Omega$  potentiometer (271-220).

U1 — 555 IC timer (276-1723).

station, W1AW. Transmission frequencies are approximately 1.818, 3.58, 7.08, 14.07, 21.08, 28.08, 50.08 and 147.555 MHz. Texts are from recent issues of *QST* and checking references are sent several times in each session. For practice purposes, the order of words in each line of text may be reversed during the 5-15 WPM transmissions. The transmission time schedule is shown in Table 2. See Chapter 38 for more information.

## A CODE-PRACTICE OSCILLATOR

The simple oscillator (see Figs. 1 and 2) is a good introduction to electronic construction as well as a useful tool for

Fig. 2 — Photograph of the code-practice oscillator. This version is available as a kit (less wooden base) from: Circuit Board Specialists, P.O. Box 969, Pueblo, CO 81002. See Chapter 24 for a discussion of construction techniques that can be used to build this circuit.

learning to send the Morse code. The costs can be cut dramatically through intelligent substitution and liberal scrounging from a ham's junk box.

The schematic diagram and photographs show the unit in detail, but exact duplication is not necessary. Construction techniques are presented in Chapter 24, and the

schematic symbols are printed near the front of this volume. The project can be assembled in an evening. This code practice oscillator is intended for beginners using hand keys. Because the circuit is keyed in the positive battery line, the oscillator may not be compatible with some electronic keyers.

# Assembling a Station

**A**lthough many hams never try to build a major project, such as a transmitter, receiver or amplifier, they do have to assemble the various components (say, for example, transceiver, power supply and antenna) into a working station. There are many benefits to be derived from assembling a safe, comfortable, easy-to-operate collection of radio gear, whether the shack is at home, in the car or portable in a field.

Rather than discuss electronic theory or individual construction projects, this chapter will detail some of the “how tos” of setting up a station for fixed, mobile and portable operation. Such topics as station location, safety, finding adequate power sources, station layout and cable routing are covered, along with some of the practical aspects of antenna erection and maintenance.

Two major themes recur throughout this chapter: Plan ahead, and most shortcuts aren't really, in the long run. The key to a successful installation, whether it's the installation of a mobile rig under the dash of your car or the erection of a 150-foot tower with a large monobander at the top, is proper planning. If you take the time to think the project through to its conclusion, to consider alternatives, to make measurements and rough sketches, your chances of success are much greater than if you start drilling and cutting blindly. You'll avoid 99 percent of such problems as “Oops, that guy wire has to go through the center of this tree,” or “Oops, I can't drive my car with the mobile rig installed because I put the rig where my left knee has to go.”

Most shortcuts will eventually come back to haunt you, so it's really worth doing a job right the first time. A “bargain” antenna mast for your tower is no bargain if it folds up in a windstorm, sending your antenna crashing to the ground. Not taking the time to weatherproof your outdoor connections is no shortcut if you have to replace a cable after six months because it filled up with water. Running your shack from an overloaded electrical service is no “deal” if the circuit breaker opens and you're off the air every time the refrigerator compressor kicks in. Plan ahead, and do

Fig. 1 — W9OBF is quite active from this compact station built into a hideaway desk. A station arranged like this can easily be tucked into the corner of a living room without disrupting the rest of the household.

the best job you can when putting together your station.

### SELECTING A LOCATION

Selecting the right location for your station is the first and perhaps most important step in assembling a safe, comfortable, convenient station. The exact location will depend on the type of home or apartment you have and how much of that space can be devoted to your station. Fortunate amateurs will have a spare room to devote to housing the station; some may even have a separate building for their exclusive use. Most aren't that lucky, however, so usually a spot in the cellar or attic, or a corner of the living room is pressed into service.

Examine the possibilities from several angles. A station should be comfortable; odds are good that you'll be spending a lot of time there over the years. Some unfinished basements are damp and drafty — not an ideal environment for several hours of leisurely hamming. Attics have their

drawbacks, too; they can be stifling during warmer months. If possible, locate your station away from the heavy traffic areas of your home. Operation of your station should not interfere with family life. A night of chasing DX on 80 meters may be exciting to you, but the other members of your household may not share your enthusiasm.

Keep in mind that you must connect your station to the outside world. The location you choose should be convenient to a good power source and an adequate ground. There should be a fairly direct route to the outside for running antenna feed lines, rotator control cables and the like.

Although most homes will not have an “ideal” space meeting all requirements, the right location for you will be obvious after you scout around. The amateurs whose stations are depicted in Figs. 1 through 3 all found the right spot for them. Weigh the tradeoffs and decide which features you can do without and which are necessary for

Fig. 2 — The basement makes a good station location if it is dry. This setup belongs to WB2NPE.

Fig. 3 — Some amateurs, like PP2ZDD, are fortunate enough to have a separate room available for their stations.

your style of operation. If possible, pick an area large enough for future expansion.

### SAFETY

Although the RF, ac and dc voltages in most amateur stations pose a potentially grave threat to life and limb, common sense and knowledge of safety practices will help you avoid accidents. Building and operating an Amateur Radio station can be, and is for almost all amateurs, a perfectly safe pastime. However, carelessness can lead to severe injury, or even death. The ideas presented here are only guidelines; it would be impossible to cover all safety precautions. Remember: There is no substitute for common sense.

A fire extinguisher is a must for the well-equipped amateur station. The fire extinguisher should be of the carbon-dioxide type to be effective in electrical fires. Store it in an easy-to-reach spot and check it at recommended intervals.

Family members should know how to turn the power off in your station. They should also know how to apply artificial respiration. Many community groups offer courses on cardiopulmonary resuscitation (CPR).

### AC and DC Safety

The primary wiring for your station should be controlled by one master switch, and other members of your household should know how to kill the power in an emergency. All equipment should be connected to a good ground. All wires carrying power around the station should be of the proper size for the current carried and be insulated for the voltage level involved. Bare wire, open-chassis construction and exposed connections are an invitation to accidents. Remember that high-current, low-voltage power sources are just as dangerous as high-voltage, low-current sources. Possibly the most-dangerous voltage source in your station is the 117-V primary supply; it is a hazard often overlooked because it is a part of everyday life. Respect even the lowliest power supply in your station.

Whenever possible, kill the power and

unplug equipment before working on it. Discharge capacitors with an insulated screwdriver; don't assume the bleeder resistors are 100 percent reliable. In a transmitter, always short the tube plate cap to ground just to be sure. If you must work on live equipment, keep one hand in your pocket. Avoid bodily contact with any grounded object to prevent your body from becoming the return path from a voltage source to ground. Use insulated tools for adjusting or moving any circuitry. Never work alone. Have someone else present; it could save your life in an emergency.

### RF Safety

An often-overlooked safety precaution is the avoidance of unnecessary exposure to RF energy. Body tissues that are subjected to large amounts of RF energy may suffer serious heat damage. At frequencies where the body's length is around 0.4 wavelength, RF energy is most efficiently absorbed; this occurs in the VHF range.

Most Amateur Radio operations use relatively low RF power, and the operations are highly intermittent. Hams spend more time listening than transmitting, and actual transmissions — like keyed CW and SSB — are inherently intermittent. The exception is RTTY, because the RF carrier is present continuously at its maximum level.

Potential exposure situations should be taken seriously. Observing these "RF awareness" guidelines will help make Amateur Radio operation safe.

- Confine RF radiation to antenna radiating elements themselves. Provide a single, good station ground (earth), and eliminate radiation from transmission lines.

- In high-power operation (several hundred watts and up) in the HF and VHF region, and particularly with RTTY, try to avoid human presence near antenna ends. With vertical monopole antennas, humans should go no closer than 10-15 feet during high-power, non-intermittent operation.

- Don't operate RF power amplifiers, especially at VHF/UHF, with the covers removed.

- In the UHF/SHF region, never look

into the open end of an activated length of waveguide or point it toward anyone. Never point a high-gain, narrow-beam-width antenna (a paraboloid, for instance) toward people.

- With mobile rigs of 10-W RF power or more, do not power your rig if anyone is standing near the antenna.

- With hand-held transceivers with RF power output above several watts, maintain an inch or so between forehead and antenna. Keep the antenna tip away from your head.

- Don't work on antennas that have RF power applied.

- Amateur antennas up on towers, well away from people, pose no exposure problem. Make sure, however, that transmission lines are not radiating.

Further details on RF safety can be found in *The Satellite Experimenter's Handbook*, published by the ARRL. *QST* carries information regarding RF environmental regulations at the local and federal levels, and tells how these regulations may affect amateur operations.

### National Electrical Code®

The *National Electrical Code®* is a comprehensive document that details safety requirements for all types of electrical installations. In addition to setting safety standards for house wiring and grounding, the Code also contains a section on Radio and Television Equipment — Article 810. Sections C and D specifically cover Amateur Transmitting and Receiving Stations. Highlights of the section concerning Amateur Radio stations follow. If you are interested in learning more about electrical safety, you may purchase a copy of *The National Electrical Code* or *The National Electrical Code® Handbook*, edited by Peter Schram, from the National Fire Protection Association, Batterymarch Park, Quincy, MA 02269.

Antenna installations are covered in some detail in the Code. It specifies minimum conductor sizes for different length wire antennas. For hard-drawn copper wire, the Code specifies no. 14 for

open (unsupported) spans less than 150 feet, and no. 10 for longer spans. Copper-clad steel, bronze or other high-strength conductors may be no. 14 for spans less than 150 feet and no. 12 for longer runs. Lead-in conductors (for open-wire transmission line) should be at least as large as those specified for antennas.

The Code also says that antenna and lead-in conductors attached to buildings must be firmly mounted at least 3 inches clear of the surface of the building on nonabsorbent insulators. The only exception to this minimum distance is when the lead-in conductors are enclosed in a "permanently and effectively grounded" metallic shield. The exception covers coaxial cable.

According to the Code, lead-in conductors (except those covered by the exception) must enter a building through a rigid, non-combustible, nonabsorbent insulating tube or bushing, through an opening provided for the purpose that provides a clearance of at least 2 inches or through a drilled window pane. All lead-in conductors to transmitting equipment must be arranged so that accidental contact is difficult.

Transmitting stations are required to have a means of draining static charges from the antenna system. An antenna discharge unit (lightning arrester) must be installed on each lead-in conductor (except where the lead-in is protected by a continuous metallic shield that is permanently and effectively grounded, or the antenna is permanently and effectively grounded). An acceptable alternative to lightning arrester installation is a switch that connects the lead-in to ground when the transmitter is not in use.

Grounding conductors are described in detail in the Code. Grounding conductors may be made from copper, aluminum, copper-clad steel, bronze or similar erosion-resistant material. Insulation is not required. The "protective grounding conductor" (main conductor running to the ground rod) must be as large as the antenna lead-in, but not smaller than no. 10. The "operating grounding conductor" (to bond equipment chassis together) must be at least no. 14. Grounding conductors must be adequately supported and arranged so that they are not easily damaged. They must run in as straight a line as practical between the mast or discharge unit and the ground rod. Adequate ground systems are covered later in this chapter.

Some information on safety inside the station is covered in the Code. All conductors inside the building must be at least 4 inches away from conductors of any lighting or signalling circuit except when they are separated from other conductors by conduit or a nonconducting material. Transmitters must be enclosed in metal cabinets, and the cabinets must be grounded. All metal handles and controls accessible by the operator must be grounded. Access doors must be fitted with

Fig. 4 — Typical LA series MOV protectors are shown at A with various connectors on the leads. A PA series MOV is shown at B as it might be mounted in a service-entrance box.

interlocks that will disconnect all voltages above 350 when the door is opened.

### Lightning Protection

The National Fire Protection Association (NFPA) publishes a booklet called *Lightning Protection Code* (NFPA no. 78-1983) that should be of interest to radio amateurs. Write to the NFPA at the address given in the previous section for information on obtaining a copy. Two paragraphs of particular interest to amateurs are presented below:

"3-26 Antennas. Radio and television masts of metal, located on a protected building, shall be bonded to the lightning protection system with a main size conductor and fittings.

"3-27 Lightning arresters, protectors or antenna discharge units shall be installed on electric and telephone service entrances and on radio and television antenna lead-ins."

The best protection from lightning is to disconnect all antennas from equipment and disconnect the equipment from the power lines. Ground antenna feed lines to safely bleed off static buildup. Eliminate the possible paths for lightning strokes. Rotator cables and other control cables from the antenna location should also be disconnected during severe electrical storms.

In some areas, the probability of lightning surges entering homes via the 117/234-V line may be high. Lightning produces both electrical and magnetic fields that vary with distance. These fields can couple into power lines and destroy electronic components. Radio equipment can be protected from these surges through the use of transient-protective devices. The following information originally appeared in a February 1982 *QST* article by Gene Collick, W8LEQ and Ken Stuart, W3VVN.

### Protective Devices

The General Electric Home Lightning Protector® is designed to prevent lightning surges (entering through the wiring) from

damaging electrical wiring and/or appliances. The protector is a two-pole, three-wire device designed primarily for single-phase 117/234-V grounded-neutral service. It mounts via a ½-inch pipe-thread connection through a knockout in the service-entrance box preferably, or, at the weather-head or within the meter housing. The purpose of this device is to reduce the amplitude of large transients.

TransZorbs® are silicon devices manufactured by General Semiconductor Industries for transient suppression. They contain a large-area PN junction having integral heat sinks and are capable of handling short-duration, high-power pulses (typically 1500 watts for 1 millisecond and 100,000 watts for 100 nanoseconds). The TransZorb® protects by clamping transient voltages to a safe level, with sub-nanosecond reaction time.

A metal-oxide varistor (MOV) is a bulk semiconductor device whose resistance varies with the magnitude (but not polarity) of the applied voltage. At extremely low currents, a varistor acts like a linear resistor with a resistance that can exceed hundreds of megohms. At higher currents, the voltage-current relation is nonlinear, and at extremely high currents the device acts like a constant resistor with a very small value (typically about 1 ohm). Varistors can respond in low-nanosecond times, with clamping-threshold voltages ranging from 10 to 1500 V, with continuous power from 0.5 to 5 watts and with peak energy of more than 600 joules. MOVs have a capacitance that is a device parameter, and this should be considered for high-frequency applications. GE manufactures devices with wire leads (LA series) and the heat-sink type (PA series). The PA type may be used for service-entrance box and fuse-mounting; use the LA units for coils, solenoids and such within the equipment. See Fig. 4.

### Installation

The first protective device you can install is a secondary low-voltage lightning arrester rated at 650 V (a typical device is a GE

Fig. 5 — Construction of a plug-in protector. Install a V130LA10A MOV across the brass and silver terminals and another across the silver and green terminals.

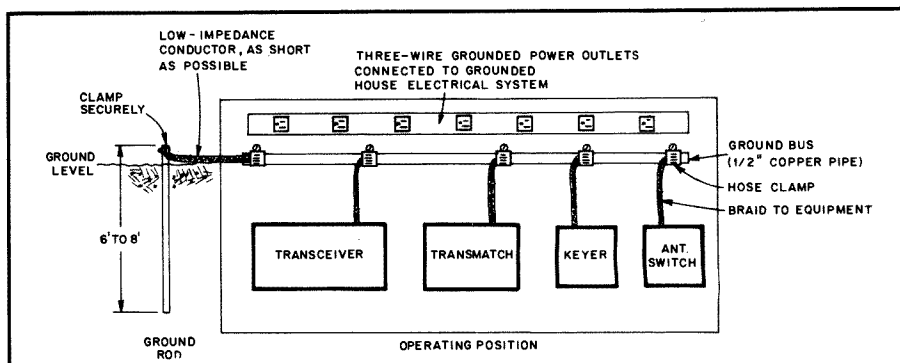

Fig. 6 — An effective station ground bonds the chassis of all equipment together with low-impedance conductors and ties into a good earth ground.

MOVs for 117-V Lines

V130LA1 — Very Light Duty (276-571)

SNR14A130K — Light Duty (276-570)

SNR20A130K — Medium Duty (276-568)

Thyrite type 9L15BC002). Power should be removed from the feed to the house, and the device should be installed ahead of the service-entrance box by a qualified electrician. The black leads (2) are connected to each hot leg, with the white lead terminated to the meter box (be sure the meter box is directly connected to the service-entrance box). The reason the white lead is terminated to the box rather than the electrical circuit neutral is that the device is being installed to protect against the common-mode (phase-to-case ground) transient.

The second device to be installed is a low-voltage surge arrester such as a GE V130PA20A MOV. These should be connected from each hot leg to case ground. The arrester should be located in a way that provides minimum lead length. These can

be installed with an active power feed to the house, but with the main breaker turned off. Connect the MOVs on the load side of the main breaker.

The ac input to the transmitter can be protected by one of two methods. The transmitter may be modified by installing a V130LA10A MOV across the ac input and another one from neutral to case ground. If you do not want to modify the transmitter, a plug-in protector can be purchased or constructed (see Fig. 5). This device is then plugged into the duplex receptacle feeding the transmitter. This method should be ideal for renters, for portable operation or to provide some protection for those who can't afford an electrician to install the other devices. Receivers, transceivers, TV sets and other electronic equipment should all be protected in a similar fashion. An alternative would be to wire an outlet box or strip with protective devices.

Rotator protection consists of installing a plug-in MOV device in one side of the duplex receptacle that the rotator remote-control unit is plugged into. The rotator control cables should terminate in a grounded metal box. Each control cable conductor should have a GE V56ZA2 MOV connected across it to case ground. If the control cable is not shielded, the same type of protective devices can be installed within the rotator. If shielded cable is used, the devices inside the rotator would not be needed. Check the voltage on the control cable and select a value of MOV rated for a safe operating voltage above the control voltage.

MOVs are available from some of the suppliers listed in Chapter 35. Some may be available from local electrical supply houses. Table 1 lists some transient-protective devices of interest to radio amateurs.

### GROUND

An effective ground system is a must for every amateur station. The mission of the ground system is twofold. First, it reduces the possibility of electrical shock if something in a piece of equipment should fail and the chassis or cabinet becomes "hot." If connected properly, three-wire

electrical systems ground the chassis, but the majority of amateur equipment still uses the ungrounded two-wire system. A ground system to prevent shock hazards is generally referred to as "dc ground."

The second job the ground system must perform is to provide a low-impedance path to ground for any stray RF current inside the station. Stray RF can cause equipment to malfunction and contributes to RFI problems. This low-impedance path is usually called "RF ground." In most stations, dc ground and RF ground are provided by the same system.

The first step in building a ground system is to bond together the chassis of all equipment in your station. Ordinary hookup wire will do for a dc ground, but for a good RF ground you need a low-impedance conductor. Copper strap, sold as "flashing copper," is excellent for this application, but it may be hard to find. Braid from coaxial cable is a popular choice; it is readily available, a low-impedance conductor and flexible.

Grounding straps can be run from equipment chassis to equipment chassis, but a more convenient approach is illustrated in Fig. 6. In this installation, a 1/2-inch-diameter copper water pipe runs the entire length of the operating bench. A thick braid (from discarded RG-8 cable) runs from each piece of equipment to a clamp on the pipe. Copper water pipe is inexpensive and available at most hardware stores and home centers. Alternatively, a strip of flashing copper may be run along the rear of the operating bench.

After the equipment is bonded to a common ground bus, the ground bus must be wired to a good earth ground. This run should be made with a heavy conductor (braid is a good choice again) and should be as short and direct as possible. The earth ground usually takes one of two forms.

In most cases, the best approach is to drive one or more ground rods into the earth at the point where the conductor from the station ground bus leaves the house. The best ground rods to use are those available from an electrical supply house. These rods are 6 to 8 feet long and are made from steel with a heavy copper plating. Do

Fig. 7 — Here is an alternative to earth ground if the station is located far from the ground point and RF in the station is a problem. Install at least one  $\frac{1}{4}$ -wavelength radial for each band used.

not depend on shorter, thinly plated rods sold by some home electronics suppliers. These rods begin to rust almost immediately after they are driven into the soil, and they become worthless within a short time. Good ground rods, while more expensive initially, offer long-term protection. If your soil is soft and contains few rocks, an acceptable alternative to "genuine" ground rods is  $\frac{1}{2}$ -inch-diameter copper water pipe. A 6- to 8-foot length of this material offers a good ground, but it may bend while being driven into the earth.

Once the ground rod is installed, clamp the conductor from the station ground bus to it with a clamp that can be tightened securely and will not rust. Copper-plated clamps made especially for this purpose are available from electrical supply houses, but a stainless-steel hose clamp will work too. Alternatively, drill several holes through the pipe and bolt the conductor in place. If a torch is available, solder the connection.

Another popular station ground is the cold water system in the building. To take advantage of this ready-made ground system, run a low-impedance conductor from the station ground bus to a convenient cold water pipe, preferably somewhere near the point where the main water supply enters the house. Avoid hot water pipes; they do not run directly into the earth. The advent of PVC (plastic) plumbing makes it mandatory to inspect the cold water system from your intended ground connection to the main inlet. PVC is an excellent insulator, so any PVC pipe or fittings rule out your cold water system for use as a station ground.

For some installations, especially those located above the first floor, a conventional ground system such as that just described will make a fine dc ground but will not provide the necessary low-impedance path to ground for RF. The length of the conductor between the ground bus and the ultimate ground point becomes a problem. For example, the ground wire may be about  $\frac{1}{4}$  wavelength (or an odd multiple of  $\frac{1}{4}$  wavelength) long on some amateur band. A  $\frac{1}{4}$ -wavelength wire acts as an impedance inverter from one end to the other. Since the grounded end is at a very low im-

pedance, the equipment end will be at a high impedance. The likely result is RF hot spots around the station while the transmitter is in operation. In this case, this ground system may be worse than having no ground at all.

An alternative RF ground system is shown in Fig. 7. No attempt is made to ground the station to an earth ground. Instead, the station ground bus is connected to a system of  $\frac{1}{4}$ -wavelength radials. Install at least one radial for each band used. Try this system if you have RF in the shack even though your equipment is connected to a conventional ground. Keep in mind, however, that while the radial ground system offers an RF ground, it will not act as a dc ground to protect you from shock hazards.

### Ground Noise

Noise in ground systems can affect our sensitive radio equipment. It is usually related to one of three problems:

- 1) Insufficient ground conductor size
- 2) Loose ground connections
- 3) Ground loops

These matters are treated in precise scientific research equipment and certain industrial instruments by attention to certain rules. The ground conductor should be at least as large as the largest conductor in the primary power circuit. Ground conductors should provide a solid connection to both ground and to the equipment being grounded. Liberal use of lockwashers and star washers is highly recommended. A loose ground connection is a tremendous source of noise, particularly in a sensitive receiving system.

Ground loops should be avoided at all costs. A short discussion of what a ground loop is and how to avoid them may lead you down the proper path. A ground loop is formed when more than one ground current is flowing in a single conductor. This commonly occurs when grounds are "daisy-chained" (series linked). The correct way to ground equipment is to bring all ground conductors out radially from a common point to either a good driven earth ground or a cold-water system.

Ground noise can affect transmitted and received signals. With the low audio levels

required to drive amateur transmitters, and the ever-increasing sensitivity of our receivers, correct grounding is critical.

### STATION POWER

Amateur Radio stations generally require a 117-V ac power source. The 117-V ac is then converted to the proper ac or dc levels required for the station equipment. Power supply theory is covered in Chapter 6. If your station is located in a room with electrical outlets, you're in luck. If your station is located in the basement, an attic, or another area without a convenient 117-V source, you will have to run a line to your operating position.

Stations with high-power amplifiers should have a 234-V ac power source in addition to the 117-V supply. Some amplifiers may be powered from 117 V, but they require current levels at that voltage that are near, or in excess of, the limits of standard house wiring. For safety, and for the best possible voltage regulation in the equipment, it is advisable to install a separate 234-V line with an appropriate current rating if you use an amplifier.

The usual line running to baseboard outlets is rated at 15 amperes. This may or may not be enough current to power your station. To determine how much current your station requires, check the ratings for each piece of gear. Usually, the manufacturer will specify the required current at 117-V; if the power consumption is rated in watts, divide that rating by 117 V to get amperes. If the total current required for your station is near 15 amperes, you need to think about running another line or upgrading the present one. Keep in mind that other rooms may be powered from the same branch of the electrical system, so the power consumption of any equipment connected to other outlets on the branch must be taken into account. Whenever possible, power your station from a separate, heavy-duty line run directly to the distribution panel.

In modern residential systems, three wires are brought in from the outside to a distribution panel (fuse panel, or circuit-breaker panel). In the three-wire system, the third wire is neutral, which is grounded. The voltage between the other two wires is usually 234, while half of this voltage appears between each wire and neutral. In a three-wire system, the three wires should be brought into the station so that the load can be distributed to keep the line balanced. The voltage across a fixed load on one side of the line will increase as the load current on the other side is increased. The rate of the increase will depend on the resistance of the neutral wire. If the resistance of the neutral wire is low, the increase will be correspondingly small. When the currents in the two circuits are balanced, no current flows in the neutral wire, and the system is operating at maximum efficiency.

If you decide to install a separate heavy-duty 117-V line or a 234-V line, consult the

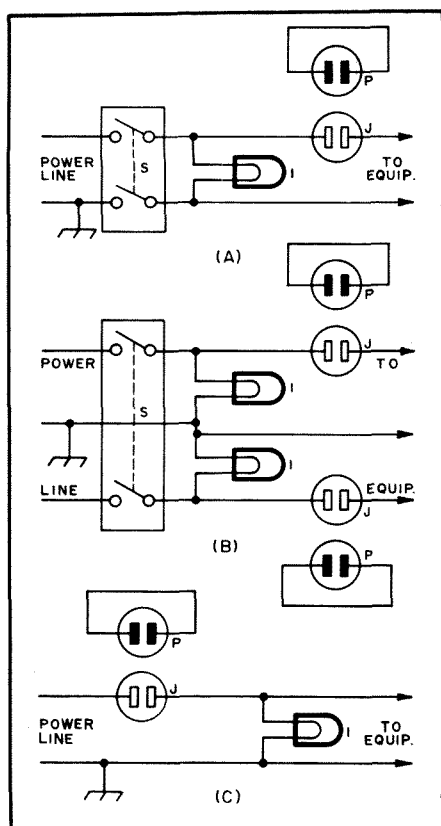

Fig. 8 — Reliable arrangements for cutting off all power to the station. S is an enclosed double-pole, double-throw power switch of appropriate ratings. J is a standard ac outlet. P is a shorted plug to fit outlet J. I is a red warning lamp. The system at A is for two-wire, 117-V lines; B is for three-wire 234-V systems; C is a simplified arrangement for low-power stations.

local power company for local requirements. In some areas, this work must be performed by a licensed electrician. You may need a special building permit for the work, and even if you are allowed to do the work yourself, you might have to get a licensed electrician to inspect the job. Your best bet is to go through the system and get the necessary permits and inspections. If something should happen, such as a fire, you might run into insurance or other problems if you didn't follow the required steps, even if the accident had nothing to do with your wiring job.

If you decide to do the job yourself, study the applicable sections of the National Electrical Code and any local building codes. This information should be available from your local building inspector. Books are available at libraries or from outlets selling electrical supplies that will tell you everything you need to know to install separate ac lines for your station. Use only good-quality wire and other materials with ratings as specified in the building codes. If you have any doubts about doing the work yourself, get a licensed electrician to do the installation.

### Safety Precautions

All power supplies in an installation

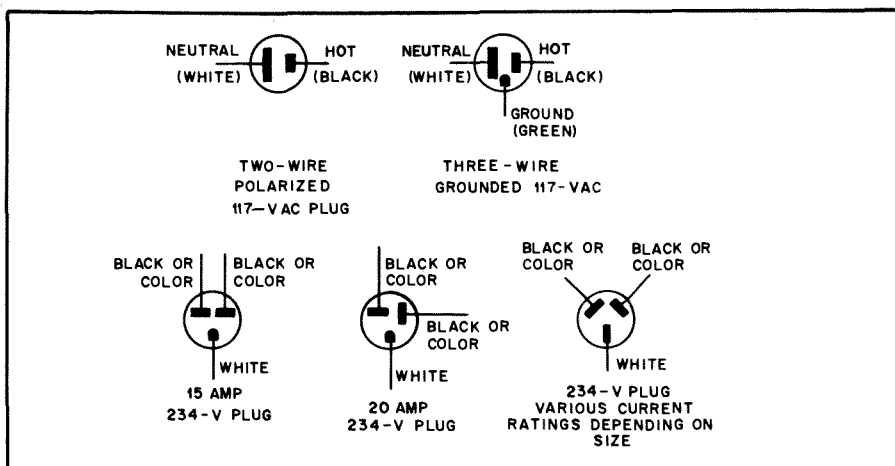

Fig. 9 — Proper wiring for power plugs found in amateur stations. Follow correct wiring procedures to minimize shock hazards. On 117-V plugs, the screw terminal or connection for one prong is brass and the other is plated ("white"). Connect the black wire to the brass prong and the white wire to the white prong. Always use 234-V connectors for 234-V systems; otherwise, you may destroy a piece of equipment by applying too much voltage.

should be fed through a single main power-line switch so that all power may be cut off quickly, either before working on the equipment, or in case of an accident. Spring-operated switches or relays are not sufficiently reliable for this important service. Foolproof devices for cutting off all power to the transmitter and other equipment are shown in Fig. 8. The arrangements shown in Figs. 8A and B are similar circuits for two-wire (117-volt) and three-wire (234-volt) systems. S is an enclosed double-throw switch of the sort usually used as the entrance switch in house installations. J is a standard ac outlet and P a shorted plug to fit the outlet. The switch should be located prominently in plain sight, and members of the household should be instructed in its location and use. I is a red lamp located alongside the switch. Its purpose is not so much to serve as a warning that the power is on as it is to help in identifying and quickly locating the switch should it become necessary for someone else to cut the power off in an emergency.

The outlet J should be placed in some corner out of sight where it will not be a temptation for children or others to play with. The shorting plug can be removed to open the power circuit if there are others around who might inadvertently throw the switch while the operator is working on the rig. If the operator takes the plug when the station is not in use, it will prevent unauthorized persons from turning on the power. Of utmost importance is the fact that the outlet J must be placed in the ungrounded side of the line.

Those who are operating low power and feel that the expense or complication of the switch isn't warranted can use the shorted-plug idea as the main power switch. In this case, the outlet should be located prominently and identified by a signal light, as shown in Fig. 8C.

The test bench should be fed through the

main power switch, or a similar arrangement at the bench, if the bench is located remotely from the transmitter.

### Three-Wire 117-V Power Cords

To meet the requirements of state and national codes, electrical tools, appliances and many items of electronic equipment now being manufactured to operate from the 117-volt line must be equipped with a three-conductor power cord. Two of the conductors carry power to the device in the usual fashion, while the third conductor is connected to the case or frame. See Fig. 9.

When plugged into a properly wired mating receptacle, the three-contact polarized plug connects this third conductor to an earth ground, thereby grounding the chassis or frame of the appliance and preventing the possibility of electrical shock to the user. All commercially manufactured items of electronic test equipment and most ac-operated amateur equipment are being supplied with these three-wire cords. Adapters are available for use where older electrical installations do not have mating receptacles. For proper grounding, the lug of the green wire protruding from the adapter must be attached underneath the screw securing the cover plate of the outlet box where connection is made, and the outlet box itself must be grounded.

### Multiple Outlets

Once you have the right line or lines running from the distribution panel to your station, you will need to bring the power to each piece of equipment. All of the accessories, such as keyer, rotator control box and clock, as well as the station transceiver, need a separate outlet. Commercial outlet strips, such as that pictured in Fig. 10, will provide a grounded outlet for each piece of equipment. If the commercially available outlet strips do not suit your setup, you can make your own.

Fig. 11 shows one way to make your own

Fig. 10 — Commercially made power strips are available with different numbers of outlets. Some feature built-in fuses or circuit breakers. Three-wire strips are recommended for use in amateur stations.

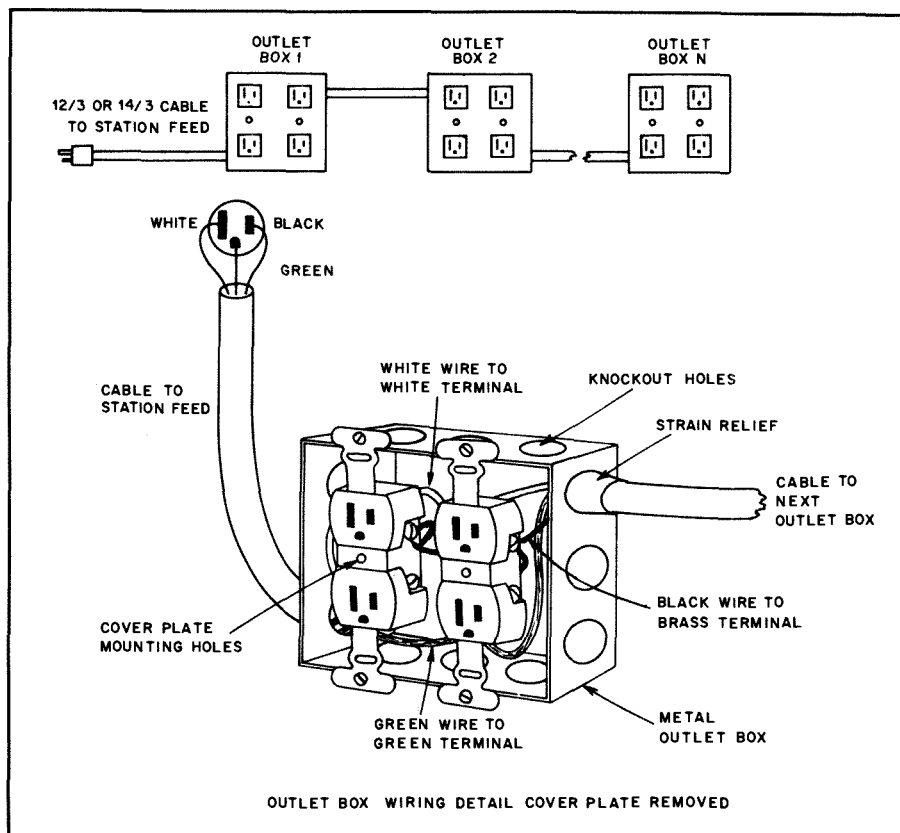

Fig. 11 — It is possible to make a custom outlet strip for your station. Space the outlets at convenient intervals for your operating position. See text for details.

outlet strip. The materials to make this type of strip are available at most hardware stores or home centers. Use wire with sufficient current rating. See Chapter 35 for a table listing the current-carrying ability of different wire sizes. No. 14 wire is rated to handle 17 amperes continuously when bundled in cables, so it is adequate for most installations. The best kind of cable to buy for this job is stranded 14/3 (three conductors, each no. 14) with a rubberized outer jacket. This type of cable is easy to work with and is flexible.

First, measure the length of cable needed to run from your operating position to the station power feed. Include enough extra so that you can run the cable neatly along the floor if necessary. Refer to Fig. 9 to see

which color wire goes to which plug terminal. Locate the first outlet box near the first group of equipment. Wire the outlets in parallel, paying close attention to where the various color conductors should go. Wire any additional outlet boxes in parallel with the first. Depending on the amount of equipment you have, you may choose either two- or four-outlet boxes. The individual outlet boxes may be left loose, attached to a strip of wood of the appropriate dimensions, or bolted directly to the operating bench.

#### STATION LAYOUT

Station layout is largely a matter of personal taste. It will depend to a large extent on the amount of space available, the

amount of gear involved and the types of operating activities engaged in. Although no two stations are exactly alike, there are some underlying considerations you should be aware of. These design considerations will help you build a convenient, easy-to-use station around your needs and means.

#### The Operating Table

The operating table may be an office desk, a kitchen table or a custom-made bench; what you use will depend on the available space and materials on hand. The two most important considerations are the size of the top and the height of the top above the floor. The top of most commercially manufactured desks is about 29 inches above the floor. This is a comfortable height for most adults. If the top is much lower, your knees may not clear the underside, and you will be sitting in an uncomfortable pitched-forward position. If the table top is much higher, you may not be able to reach the equipment, and writing will be awkward.

The dimensions of the top of the operating table are a prime consideration. Although the top need be only deep enough to hold the equipment (a foot or so), a much wider top greatly enhances the comfort and convenience of your operation. Leaving room for a power outlet strip at the back of the table, a ground bus, the equipment and room for writing, the depth of a comfortable operating table grows to at least 36 inches, and preferably more. For an ideal operating table, 42 to 48 inches is about the right depth. See Fig. 12. The length of the top will depend on how much equipment is used.

An office desk makes a good operating table. The top is usually 30 to 36 inches deep by 60 inches wide. The drawers can be put to good use for log books, headphones and the like.

#### A Homemade Operating Table

An unfinished flush-type door, measuring approximately 30 × 84 inches, makes an acceptable operating bench if the power outlet strip and ground bus are not mounted on the table top. A depth of 30 inches is just enough for the equipment and writing area. The door may be mounted on two 2-drawer bench cabinets (see Fig. 13), making an easy bench with drawer space.

A flush door may also be made into an attractive homemade table. Fig. 14 shows construction details for building a simple but sturdy homemade operating table. Side members for supporting the top are made from ordinary 2 × 3 lumber which comes in standard lengths of 8 and 12 feet. Making legs that are good and solid isn't the easiest job in the world, and if the table isn't solid it will be a poor operating desk. You can get around this by using the construction technique shown in Fig. 14A and D. The 2 × 3s are formed into a square or rectangular format, as shown at A. Each

Fig. 12 — The ideal operating table is about 42 inches deep and as wide as you need to make it to fit your available space. This arrangement leaves plenty of room for equipment and cables, with lots of elbow room for comfort.

Fig. 13 — Two file cabinets and a flush-type door make an effective operating bench.

Fig. 14 — A flush door may also be used with a simple frame to make a furniture-quality operating table. (A) 2 x 3 lumber is used to form the side supports. Each joint should be glued and then screwed together. (B) Front, top and side views detailing the method of fastening the side supports to the top. (C) Completely fill the space around the bolt head with epoxy. (D) Table assembly and side covering information. (E) The rear-apron brace should be attached to both side members at the top of the desk.

joint should be glued and screwed together. Nails will not provide enough sturdiness.

Once the glue holding the 2 x 3s together has completely dried (several hours is sufficient with most types of glue), these assemblies can be drilled and made ready for mounting. If you are planning to cover the top and edges of the door with a plastic laminate, such as Formica, holes should be drilled through the door and countersunk as shown in Fig. 14B. After the holes in the door have been drilled, place the pieces in the final position. Drill through the 2 x 3s at the four bolt locations. After these holes have been drilled, the four bolts should be inserted in the holes, through the 2 x 3s and secured by flat washers and nuts. With the bolts securely in place, fill the gaps between the bolt heads and wood with epoxy cement. See Fig. 14C.

Once the epoxy has hardened (it's a good idea to let it set overnight), the nuts can be removed and the three sections taken apart. If you are planning on having the top laminated, now is the time. Most kitchen cabinet shops can do this for you, as they have all of the necessary tools. Pick a color that compliments the rest of the shack!

The table is now ready for assembly. Place the table top on its good surface with the bolts sticking up. Now the side members can be slipped over the bolts and held in place with flat washers, lock washers and nuts. Make sure to tighten the nuts securely.

At this point, the side coverings can be attached to the leg assemblies. Ordinary 1/4-inch plywood or Masonite can be used if you plan on painting this portion of the table. An alternative would be to use oak-, walnut-, birch- or teak-veneered plywood. Although this material is a bit more expensive than ordinary plywood, it yields a quality furniture-like appearance. The wood can be stained and coated with clear lacquer to preserve the finish. Another alternative would be to use pieces of wood paneling for the side coverings. In any case, the coverings on the outside of the table should be glued and tacked to the frame. The inner side coverings should be framed only to the frame so they can be removed and the table taken apart should the need arise. The front face of the side members

Fig. 15 — A simple but very strong equipment shelf can be built from  $\frac{3}{4}$ -inch plywood. See text for details.

Fig. 16 — Example station layout as seen from the front (A) and the top (B). The equipment is spaced far enough apart that air circulates on all sides of each cabinet. Equipment that is adjusted frequently sits on the table top, while equipment requiring infrequent adjustment is perched on a shelf. All equipment is positioned so that the operator does not have to move the chair to reach anything at the operating position.

should be covered with a wide strip of veneer or plastic laminate of the same color used for the top of the table.

A rear-apron brace can be made from a  $2 \times 4$ . By painting this brace flat black it will not detract from the appearance of the table even if a small amount of its surface shows. The power outlet strip and ground bus can be attached to the rear-apron brace.

If you have some basic woodworking

tools and knowledge, you can construct a larger top for your operating table and mount it on the type of framework just described. The homemade top is fashioned from a single  $4 \times 8$ -foot sheet of plywood or particle board. Particle board is less expensive than plywood. Its perfectly smooth, even surface makes a good base for plastic laminates, but it is substantially heavier than plywood and not as strong. Depending on your needs, you may use the

entire sheet for your table top, or you may trim it to size. If you make the top at least 42 inches deep, you will have plenty of room for setting up the equipment.

The type of finish you select for your top will depend on the material used. Plastic laminates, while expensive, are attractive and durable; they also make an excellent writing surface and are easy to keep clean. Plywood may be stained and finished with a tough varnish, or it may be painted. If you paint or varnish particle board or plywood, you should use a piece of glass or other hard material as a writing surface.

### Stacking Equipment

No matter how large your operating table is, some vertical stacking of equipment is necessary if you are to reach everything from your chair. Piling the equipment cabinets one on top of another is not a particularly good idea because most amateur equipment needs air flowing around it for cooling. Construction of a shelf like that shown in Fig. 15 will improve equipment layout in most installations.

The exact shelf dimensions will depend on the size of your operating table and the size of your equipment. This shelf is completely open both front and back and has no center support; access to equipment and interconnecting cables is excellent. The shelf should be made from strong material, such as  $\frac{3}{4}$ -inch plywood. A shelf constructed like that shown in Fig. 15 will support several hundred pounds without bowing in the center. The top, sides and apron braces are all made from  $\frac{3}{4}$ -inch plywood. The top and side dimensions can be varied to match your station requirements. Glue and screw all adjoining surfaces for maximum strength. Finish the shelf to match the operating table. If you build it right, you should be able to stand on the shelf without it bending.

### Arranging the Equipment

When you have acquired the operating table and shelving for your station, the next task is arranging the equipment in a convenient, orderly manner. The first step is to provide power outlets and a good ground as described in a previous section. Be conservative in estimating the number of power outlets for your installation; radio equipment has a habit of multiplying with time, so plan for the future at the outset.

Fig. 16 illustrates a sample station layout. The rear of the operating table is spaced about  $1\frac{1}{2}$  feet from the wall to allow easy access to the rear of the equipment. This installation incorporates two separate operating positions, one for HF and one for VHF. When the operator is seated at the HF operating position, the keyer and transceiver controls are within easy reach. The keyer, keyer paddle and transceiver are the most-often adjusted pieces of equipment in the station. The speaker is positioned right in front of the operator for the best possible reception.

Fig. 17 — This station, owned by K5RC, was designed with contest operation in mind. Note the high-efficiency layout; separate rigs for each band makes for quick band changes. Control switches, keyer and rig are all within easy reach.

Fig. 18 — WA3AXV is interested primarily in VHF work. Each band requires a separate transverter and amplifier. This equipment, all of which is rarely touched once adjusted, is located above the operating table. The transceiver used as a tuneable IF and the accessories are within easy reach.

Fig. 19 — K1JX has an HF operating position and a VHF operating position arranged on a corner table.

Accessory equipment not often adjusted, including the amplifier, antenna switch and rotator control box, is located on the shelf above the transceiver. The SWR/power meter and clock, often consulted but rarely touched, are located where the operator can view them without head movement. All HF-related equipment can be reached without moving the chair.

This layout assumes that the operator is right-handed. The keyer paddle is operated with the right hand, and the keyer speed

and transceiver controls are operated with the left hand. This setup allows the operator to write or send with the right hand without having to cross hands to adjust the controls. If the operator is left-handed, some repositioning of equipment is necessary, but the idea is the same. For best results during CW operation, the paddle should be weighted to keep it from "walking" across the table. It should be oriented such that the operator's entire arm from wrist to elbow rests on the table top to prevent fatigue.

Some operators prefer to place the station transceiver on the shelf to leave the table top clear for writing. This arrangement leads to fatigue from having an unsupported arm in the air most of the time. If you rest your elbows on the table top, they will quickly become sore. If you rarely operate for prolonged periods, however, you may not be inconvenienced by having the transceiver on the shelf. The real secret to having a clear table top for logging, etc., is to make the operating table deep enough that your entire arm from elbow to wrist rests on the table with the front panels of the equipment at your fingertips. This leaves plenty of room for paperwork, even with a microphone and keyer paddle on the table.

The VHF operating position in this station is similar to the HF position. The amplifier and power supply are located on the shelf. The station triband beam and VHF beam are on the same tower, so the rotator control box is located where it can be seen and reached from both operating positions. This operator is active on packet radio on a local VHF repeater, so the computer, printer, terminal node controller and modem are all clustered within easy reach of the VHF transceiver.

This sample layout is intended to give you ideas for designing your own station. Study the photos of station layouts presented here, in other chapters of this Handbook and in *QST*. Visit the shacks of amateur friends to view their ideas. Station layout is always changing as you acquire new gear, dispose of old gear, change operating habits and interests, or become active on different bands. Configure the station to suit your interests, and keep thinking of ways to refine the layout. Figs. 17 through 19 show station arrangements tailored for specific purposes.

## INTERCONNECTING YOUR EQUIPMENT

After you've chosen the equipment for your station and arrived at a layout, you'll have to interconnect everything. The complexity of the wiring job depends on the setup; but large or small, HF or VHF, high or low power, every shack needs some cabling between equipment. Commercially manufactured cables with connectors are available for some applications. In most instances, however, there will not be a readily available cable, so you'll have to make your

own. Making custom cables is not difficult. Most equipment manuals tell you the pin-outs for microphone, key, accessory and control connectors. Many manufacturers include connectors, but they leave the cable construction up to you so you can make up the right lengths for your installation.

You should use good wire, cables and connectors in your shack. Take the time to make good mechanical and electrical connections on your cable ends. Poorly made cables are a source of trouble. Connections may break, requiring maintenance. Improperly assembled transmission-line connectors can cause RFI. More important, cables made from inferior materials or assembled sloppily are a safety hazard. Wire too small for the current load can heat up, presenting a fire hazard. Connections lacking mechanical integrity can work free, possibly shorting a power supply to ground or applying voltage where not expected. Wire with poor or underrated insulation is a shock hazard.

Wherever possible, neatly bundle your wires and cables. There are many ways to do this. Some amateurs use masking tape or cloth adhesive tape. Others use paper labels attached to the cables with string. See Fig. 20. Whatever method you use, proper labeling makes disconnecting, reconnecting or rearranging equipment much easier. Good labels will also help you avoid inadvertently putting voltage where it doesn't belong.

## Types of Wire and Cable

The type of wire or cable to use depends on the job at hand. If the wire is to carry any significant current, check the wire table in Chapter 35 for the ratings of different sizes. For safety, always use wire heavy enough for the task. Also, check the insulation rating. Almost any insulation will do for low voltages, but use the right wire for higher voltages; anything you can do to minimize shock hazards around your shack is important for your safety.

Use the right size coaxial cable for connecting transmitters, transceivers, antenna switches, SWR bridges, Transmatches and the like. For example, RG-58/U cable is fine between your transceiver and SWR meter, but it is too small to use between your legal-limit amplifier and Transmatch. Chapter 16 contains information on the characteristics of popular coaxial cables.

Hookup wire may be stranded or solid. Generally, stranded wire is the better choice for most applications because solid wire will break under repeated flexing.

Many interconnections should be made from shielded wire to reduce the chances of RF getting into equipment. RG-174/U subminiature coaxial cable is a good choice for control, audio and some power leads. It is shielded, small and very flexible. Fig. 21 shows how to prepare coaxial cable for attachment to a connector.

## Connectors

Connectors found in amateur stations

Fig. 20 — Labels on the cables make it much easier to rearrange things in the station. Labeling ideas include masking tape, cardboard labels attached with string and labels attached to fasteners found on plastic bags (such as bread bags).

run the gamut from single-conductor ring terminals for use on terminal blocks, to four-conductor microphone connectors, to 50-conductor ribbon cable connectors. Although the number of connectors in existence is mind boggling, most manufacturers of amateur gear use a few standard types. If you are involved in any group activities, such as public service and emergency preparedness work, check to see what kinds of connectors others in the group use. If group members standardize whenever possible, the equipment will be more interchangeable — a definite plus in an emergency.

#### Audio, Power and Control Connectors

The simplest form of connector is found on terminal blocks. Although it is possible to strip the insulation from wire and wrap it around the screw, this method leaves something to be desired. Sometimes it is difficult to hold the wire in place when tightening the screw; this is especially troublesome when the wire is large compared to the screw size, which is frequently the case. It's not always easy to get a good connection. Changing the wire on a terminal block can be a headache with the strip-and-wrap method. Also, the conductors in stranded wire tend to separate under compression, making an unsightly mess.

Fortunately, the terminal lugs illustrated in Fig. 22 eliminate these problems. These lugs may be soldered or crimped (with the right tool), or both. A good crimping tool compresses the top and bottom while keeping the sides from expanding, making a secure connection. Terminal lugs are available in different sizes; you'll get the best mechanical and electrical connection if you use the right size for your wire. Lugs are available with or without insulation. The uninsulated kind usually cost less, and you can use heat-shrink tubing after installation on the wire if insulation is necessary. The fully closed ring terminals will hold even if the screw works loose, but they require you to remove the screw completely from the block during installation. The U-shaped spade lugs are easier to install, requiring you only to remove the screw partially, but they may fall off if the

Fig. 21 — Preparing coaxial cable for use with a connector involves a few easy steps. A — Remove the outer insulation with a sharp knife or wire stripper. If you nick the braid, start over. B — Push the braid accordion-fashion against the outer jacket. C — Spread the shield strands at the point where the outer insulation ends. D — Fish the center conductor through the opening in the braid. Smooth the braid. Now strip the center conductor insulation back far enough for the type of connector you're using and tin both center conductor and shield. Be careful not to use too much solder, making the conductors inflexible. A pair of pliers used as a heat sink will help. The outer jacket removed in step A makes a perfect insulator for the braid if necessary.

Fig. 22 — The wires on one side of this terminal block have connectors; the others do not. The connectors make it possible to secure different wire sizes to the strip and also make it much easier to change things around.

screw loosens. The hook type combines the best qualities of the ring and spade terminals.

Some common multi-pin connectors are illustrated in Fig. 23. The connector shown in Fig. 23A, often called a "Cinch-Jones plug," is frequently used for cabling between equipment and outboard power supplies. Supplying from two to eight or more conductors, these connectors are keyed to go together only one way. They offer a good electrical and mechanical connection, and the pins are large enough to handle high current. If your cable is too small for the strain relief, build up the outer jacket with a few layers of tape until the strain relief clamps down securely. Properly used, the strain relief will keep your wires from breaking away from the connector because of excessive flexing of the soldered joint or from a sudden tug on the cable.

The plug shown in Fig. 23B is usually called a "molex" connector. This device consists of an insulated outer shell, resembling a honeycomb, which houses many individual male or female "fingers." Each finger is individually soldered or crimped onto a conductor of the cable and

Fig. 23 — The plug shown at A is often used to connect equipment to remote power supplies. The multi-pin connector at B is used for control, signal and power lines. The DIN plug at C offers shielding and is often used for connecting accessories to transceivers.

then inserted into the shell, locking into place. These connectors are available for different wire sizes and are used on many brands of amateur gear for power and accessory interconnections.

Fig. 23C shows a DIN connector. Commonly available with five, seven or eight pins, these connectors are a European standard that have found favor with amateur equipment manufacturers the world over. They are generally used for accessory connectors.

The connector shown in Fig. 24 is a 1/4-inch phone plug, often just called a phone plug. Usually used on amateur equipment for headphones and Morse key lines, phone plugs have two or three circuits. They are available with plastic and metal bodies. Besides offering a shielded connection, the metal-jacketed version is more durable — it won't break when stepped on!

Fig. 24 also shows a 1/8-inch phone plug, often called a miniature phone plug. Used for earphone, external speaker, key and control lines, mini-phone plugs are available in shielded and unshielded forms. An even smaller phone plug, the 1/16-inch, or subminiature, version is not common on amateur gear.

The phono, or RCA, plug illustrated in Fig. 25 is a favorite among amateurs. Phono plugs are found on amateur equipment for everything from amplifier relay control lines, to low-voltage power lines, to low-level RF lines, to antenna lines. Several styles of phono plugs are available, but the best choice for general use is the shielded type with a screw-on metal body. These plugs are much easier to grip when plugging and unplugging; they are shielded, and more durable.

Microphone connectors seem to change with the wind, and the two most popular types used today are shown in Fig. 26. At one time, microphone connectors used three conductors — one for audio, one for the PTT switch, and one for ground. Today's microphone connectors offer four or eight conductors. In many rigs, the PTT switch does not short to a common ground, but rather closes two contacts independent of ground. Some manufacturers offer a limited amount of frequency control — UP and DOWN — from switches on the mic, while others use a preamplifier in the microphone that derives its power from the rig; hence the move to eight-conductor mic connectors. When hooking up a mic to your rig, consult the manual. You should be aware of the manufacturer's recommended wiring for best results.

Some amateurs own more than one rig but have only one mic. Rather than lopping off the connector at each rig change, you can make adapters with short pieces of cable that route the signals from one mic to the right pins for several rigs. Check your local dealer; you may be surprised at the variety of male and

female mic connectors available.

## RF Connectors

There are many different types of RF connectors for coaxial cable on the market, but the three most common for amateur use are the UHF, Type N and BNC families. The type of connector used for a specific job depends on the size of the cable, the frequency of operation and the power levels involved.

The UHF connector is found on most HF and some VHF equipment. It is the only connector many hams will ever see on coaxial cable. PL-259 is another name for the UHF male, and the female is also known as the SO-239. These connectors are rated for full legal amateur power at HF. They are poor for UHF work because they do not present a constant impedance, so the UHF label is a misnomer. PL-259 connectors are designed to fit RG-8 and RG-11 size cable (0.405-in OD). Adapters are available for use with RG-58 and RG-59 size cable. UHF connectors are not weatherproof.

Fig. 27 shows how to install the solder type of PL-259 on RG-8 type cable. Proper preparation of the cable end is the key to success. Follow these simple steps. Measure back about 3/4-inch from the cable end and slightly score the outer jacket around its circumference. With a sharp knife, cut through the outer jacket, through the braid, and through the dielectric, right down to the center conductor. Be careful not to score the center conductor. Cutting through all outer layers at once keeps the braid from separating. Pull the severed outer jacket, braid and dielectric off the end of the cable as one piece. Inspect the area around the cut, looking for any strands of braid hanging loose, and snip them off. There won't be any if your knife was sharp enough. Next, score the outer jacket about 5/16-in back from the first cut. Cut through the jacket lightly; do not score the braid. This step takes practice. If you score the braid, start again. Remove the outer jacket.

Tin the exposed braid and center conductor, but apply the solder sparingly and avoid melting the dielectric. Slide the coupling ring onto the cable. Screw the connector body onto the cable. If you prepared the cable to the right dimensions, the center conductor will protrude through the center pin, the braid will show through the solder holes, and the body will actually thread onto the outer cable jacket.

Solder the braid through the solder holes. Solder through all four holes; poor connection to the braid is the most common form of PL-259 failure. A good connection between connector and braid is just as important as that between center conductor and connector. Use a large soldering iron for this job. With practice, you'll learn how much heat to use. If you use too little heat, the solder will bead up, not really flowing onto the connector body. If you use too

Fig. 24 — The phone-plug family. The 1/4-inch type is often used for headphone and key connections on amateur equipment. The three-circuit version is used with stereo headphones. The mini phone plug is commonly used for connecting external speakers to receivers and transceivers. A submini-phone plug is shown in the foreground for comparison. The shielded style with metal barrel is more durable than the plastic style.

Fig. 25 — Phono plugs have countless uses around the shack. They are small and shielded; the type with the metal body is easy to grip. Be careful not to use too much heat when soldering the ground (outer) conductor — you may melt the insulation.

Fig. 26 — The four-pin mic connector is common on modern transmitters and receivers. More elaborate rigs use the eight-pin type. The extra conductors may be used for switches to remotely control the frequency or to power a preamplifier built into the mic case.

much heat, the dielectric will melt, letting the braid and center conductor touch. Most PL-259s are nickel plated, but there are available slightly more expensive connectors with silver-plated bodies. These are much easier to solder.

Solder the center conductor to the center pin. The solder should flow on the inside, not the outside of the center pin. If you wait until the connector body cools off from soldering the braid, you'll have less trouble with the dielectric melting. Trim the center conductor to be even with the end

Fig. 27 — The PL-259, or UHF, connector is almost universal for amateur HF work and is popular for equipment operating in the VHF range. Steps A through E are described in detail in the text.

#### 83-58FCP

1. Strip cable — *don't nick braid, dielectric or conductor*. Slide ferrule, then coupling ring on cable. *Flare braid slightly by rotating conductor and dielectric in circular motion.*

2. Slide body on dielectric, barb going under braid until flange is against outer jacket. Braid will fan out against body flange.

3. Slide nut over body. Grasp cable with hand and push ferrule over barb until braid is captured between ferrule and body flange. Squeeze crimp tip only of center contact with pliers; alternate-solder tip.

#### 83-1SP (PL-259) PLUG WITH ADAPTERS (UG-176/U OR UG-175/U)

1) Cut end of cable even. Remove vinyl jacket 3/4" — *don't nick braid*. Slide coupling ring and adapter on cable.

2) Fan braid slightly and fold back over cable.

3) Position adapter to dimension shown. Press braid down over body of adapter and trim to 3/8". Bare 5/8" of conductor. Tin exposed center conductor.

4) Screw the plug assembly on adapter. Solder braid to shell through solder holes. Solder conductor to contact sleeve.

5) Screw coupling ring on plug assembly.

Fig. 28 — Crimp-on connectors and adapters for use with standard PL-259 connectors are popular for connecting to RG-58 and RG-59 type cable. This material courtesy of Amphenol Electronic Components, RF Division, Bunker Ramo Corp.

of the center pin. Use a small file to round the end, removing any solder that built up on the outer surface of the center pin. Use a sharp knife, very fine sandpaper or steel

wool to remove any solder flux from the outer surface of the center pin. Screw the coupling onto the body, and you're finished.

Fig. 28 shows two options available if you want to use RG-58 or RG-59 size cable with PL-259 connectors. The crimp-on connectors manufactured specially for the

smaller cable work very well if installed correctly. The alternative method involves using adapters for the smaller cable with standard RG-8 size PL-259s. Prepare the cable as shown. Once the braid is prepared, screw the adapter into the PL-259 shell and finish the job as you would a PL-259 on RG-8 cable.

The BNC connectors illustrated in Fig. 29 are popular for low power levels at VHF and UHF. They accept RG-58 and RG-59 cable, and are available for cable mounting in both male and female versions. There are several different styles available, so be sure to use the dimensions for the type you have. Follow the installation instructions carefully. If you prepare the cable to the wrong dimensions, the

center pin will not seat properly with connectors of the opposite sex. Sharp scissors are a big help for trimming the braid evenly. Properly assembled, BNC connectors are weatherproof.

The Type N connector, illustrated in Fig. 30, is a must for high-power VHF and UHF operation. N connectors are available in male and female versions for cable mounting and are designed for RG-8 size cable. Unlike UHF connectors, they are designed to maintain a constant impedance at cable joints. Like BNC connectors, it is important to prepare the cable to the right dimensions. The center pin must be positioned correctly to mate with the center pin of connectors of the opposite sex. Use the

right dimensions for the connector style you have. These connectors are weather-proof.

### Computer Connectors

Adding computer equipment to your shack introduces you to many potentially confusing connectors. Most of the connections between computers and their peripheral equipment are made with multi-conductor ribbon cable (Fig. 31), with 10 or more individual conductors. Although the computer industry has tried to standardize connectors, there are dozens of types of connectors in use. Some of the common ribbon cable connectors are shown in Fig. 32. Fortunately, these connectors can be divided into three categories,

## BNC CONNECTORS

### Standard Clamp

1. Cut cable and even. Strip jacket. Fray braid and strip dielectric. *Don't nick braid or center conductor.* Tin center conductor.

2. Taper braid. Slide nut, washer, gasket and clamp over braid. Clamp inner shoulder should fit squarely against end of jacket.

3. With clamp in place, comb out braid, fold back smooth as shown. Trim center conductor.

4. Solder contact on conductor through solder hole. Contact should butt against dielectric. Remove excess solder from outside of contact. Avoid excess heat to prevent swollen dielectric which would interfere with connector body.

5. Push assembly into body. Screw nut into body with wrench until tight. *Don't rotate body on cable to tighten.*

### Improved Clamp

Follow 1, 2, 3 and 4 in BNC connectors (standard clamp) except as noted. Strip cable as shown. Slide gasket on cable with *groove facing clamp*. Slide clamp on cable with *sharp edge facing gasket*. Clamp should cut gasket to seal properly.

### C. C. Clamp

1) Follow steps 1, 2 and 3 as outlined for the standard-clamp BNC connector.

2) Slide on the bushing, rear insulator and contact. The parts must butt securely against each other, as shown.

3) Solder the center conductor to the contact. Remove flux and excess solder.

4) Slide the front insulator over the contact, making sure it butts against the contact shoulder.

5) Insert the prepared cable end into the connector body and tighten the nut. Make sure that the sharp edge of the clamp seats properly in the gasket.

Fig. 29 — BNC connectors are common on VHF and UHF equipment at low power levels. (courtesy Amphenol Electronic Components, RF Division, Bunker Ramo Corp.)

based on how they are attached to ribbon cable: insulation displacement, solder-type and crimp-type.

### Insulation Displacement Connectors

An insulation displacement connector (IDC) has three parts: the body, the cover and the strain-relief clamp (Fig. 33). On the

body of an IDC there are one or more rows of metal clips — one clip for each conductor in the connector. When ribbon cable is pressed on to the body of the connector, each clip cuts through the insulation around one of the ribbon cable conductors, making contact to that conductor (Fig. 34). The IDC cover applies even pressure during

installation of the connector, and clamps the connector in place during use. Some IDCs are also provided with strain-relief clamps so that strain on the cable will not be transferred to the insulation-displacing clips.

To install an IDC, select the appropriate ribbon cable; place it on the back of the

## TYPE N CONNECTORS

### Standard Clamp

1) Cut cable and even. Remove 9/16" of vinyl jacket. When using double-shielded cable remove 5/8".

2) Comb out copper braid as shown. Cut off dielectric 7/32" from end. Tin center conductor.

3) Taper braid as shown. Slide nut, washer and gasket over vinyl jacket. Slide clamp over braid with internal shoulder of clamp flush against end of vinyl jacket. When assembling connectors with gland, be sure knife-edge is toward end of cable and groove in gasket is toward the gland.

4) Smooth braid back over clamp and trim. Soft-solder contact to center conductor. Avoid use of excessive heat and solder. See that end of dielectric is clean. Contact must be flush against dielectric. Outside of contact must be free of solder. Female contact is shown; procedure is similar for male contact.

5) Slide body into place carefully so that contact enters hole in insulator (male contact shown). Face of dielectric must be flush against insulator. Slide completed assembly into body by pushing nut. When nut is in place, tighten with wrenches. In connectors with gland, knife edge should cut gasket in half by tightening sufficiently.

### Improved Clamp

1) Follow instructions 1 through 4 as detailed in the standard clamp (be sure to use the correct dimensions).

2) Slide the body over the prepared cable end. Make sure the sharp edges of the clamp seat properly in the gasket. Tighten the nut.

### C. C. Clamp

1) Follow instructions 1 through 3 as outlined for the standard-clamp Type N connector.

2) Slide on the washer, rear insulator and contact. The parts must butt securely against each other.

3) Solder the center conductor to the contact. Remove flux and excess solder.

4) Slide the front insulator over the contact, making sure it butts against the contact shoulder.

5) Insert the prepared cable end into the connector body and tighten the nut. Make sure the sharp edge of the clamp seats properly in the gasket.

Fig. 30 — Type N connectors are a must for high-power VHF and UHF operation. (courtesy Amphenol Electronic Components, RF Division, Bunker Ramo.)

Fig. 31 — Ribbon cable with various numbers of conductors is used to interconnect computer equipment.

Fig. 34 — Installation of ribbon cable on an IDC. See text for details.

connector, making sure each conductor is in the jaws of one of the clips; place the cover on the connector and apply sufficient pressure to seat the cover. Use a vice to apply even pressure across the cover. If the connector has a strain-relief clamp, route the cable through the clamp, as shown in Fig. 35.

IDCs are the easiest ribbon cable connectors to install. If there is an IDC available for your application, use it.

### Solder-Type Connectors

Each conductor from the ribbon cable must be soldered to a tap or post in solder-type connectors (Fig. 36). Use a razor or sidecutters to separate the conductors of the ribbon cable by cutting the insulation parallel to and between the conductors. The length of cable that should be separated into individual conductors will depend on the width of the cable and the width of the connector. Assure yourself that each conductor will reach the correct pin on the connector. Once you have separated the conductors, strip and tin each one. Then solder the conductors to the appropriate pins. Use good soldering techniques.

### Crimp-Type Connectors

Each conductor in the cable is crimped to a contact; the contacts are inserted into a plastic housing (Fig. 37). The contacts can be either male (plugs) or female (sockets). Preparing ribbon cable for a crimp-type connector is the same as preparing cable for solder-type connectors, except that the stripped conductors should not be tinned. Insert each conductor into a contact and crimp the contact closed around the conductor. Properly crimped contacts should provide secure mechanical and electrical connections. Unfortunately, proper crimping is hard to achieve without the appropriate, expensive crimping tool. Therefore, many amateurs solder wires to crimp type contacts. If you choose to do this, use good soldering technique and be sure not to fill the locking tab(s) on the contact with solder.

Once the contacts are attached to the cable, use a pair of pliers to insert them in the housing. With some connectors you must be sure that the locking tab on the contact will engage the locking slot on the housing. If you insert the contacts backward, the locking tab will prevent complete insertion of the contact.

Computer cabling is often complicated. Time spent on proper selection and installation of connectors will be paid back in time saved on troubleshooting and recabling.

### ROUTING ANTENNA CABLES

Once you have interconnected the equipment in your station, the next step is getting transmission lines, rotator cables and control lines outside to the devices at the other end. The exact method you use will depend on the location of your station and the construction of your house. Use the informa-

tion presented here for ideas for your station.

The run from the shack to the antennas should be as short as possible to minimize feed-line loss and control-cable voltage drop. The most direct route may be to open a window and run the cables outside. Fig. 38 shows a way to do this and still seal your house against the weather (and bugs). Apply a piece of thick foam weatherstripping to the lower sash bottom rail and another to the sill. Adhesive-backed weatherstripping is available in various sizes at hardware stores. For this job, the thicker the better. The foam not only seals the area around the cables, but also protects the cables from being crushed or cut by the window.

On many double-hung windows, meeting rails on the top and bottom sashes no longer meet with the window partially open, so more weatherstripping is needed to seal the gap. You'll also have to devise another way to lock the window. Blocks of wood between the sash and sill will do the trick. Running cables through open windows leaves something to be desired in terms of weatherproofing and security, but it is easy and leaves no permanent scars on the house.

Another popular approach is to replace a glass window pane with material that can be drilled, such as acrylic or aluminum sheet. Fig. 39 shows how to run cables through a window with one glass pane replaced by acrylic sheet. Each piece of coaxial cable from the antennas connects to a double-female bulkhead connector. Bulkhead connectors are similar to double-female barrel connectors except they are longer and the outer body is threaded to accept nuts. UHF and Type N bulkhead connectors are commonly available at electronics part stores. Rotator and other control cables are run through holes in the window just large enough to clear the outer jacket. If additional weatherproofing is needed, run a bead of silicone seal around the cable jacket or use a grommet of the right dimensions. The multiconductor cable runs directly to a terminal strip; from there, another wire runs to the control box. Open-wire line or single conductors may be run safely through the window using ceramic feedthrough insulators. This method offers a neat, weatherproof way to run cables between your station and antennas. The original window pane may be reinstalled at any time, so there are no permanent scars. The only drawback is that you may lose the use of the window.

Fig. 40 shows how to use a dryer vent pipe to bring cables into a house. The vent pipe may be installed in a hole bored through the wall of the house, or it may be mounted in an acrylic or aluminum replacement window pane. The vent pipe hood keeps rain out of the tube, and a bead of caulk around the outside of the tube where it passes through the wall completes weather sealing. A standard three-inch vent

Fig. 35 — Completed IDC with ribbon cable, showing proper strain-relief.

pipe will pass more than enough cables for the average amateur station. The vent-pipe approach does not require cables to be broken, and the number of cables may be changed at any time without drilling more holes. For the VHF/UHF operator, it allows a continuous run of hardline from the antenna to the station. It's a good idea to stuff the pipe with insulation after installing the cables to keep small animals and insects out of the house and heat in.

### DOCUMENTING YOUR STATION

An often neglected but very important part of putting together your station is properly documenting your work. Ideally, you should diagram your entire station from the ac power lines to the antenna on paper and keep the information in a special notebook with sections for the various facets of your installation. Having the station well documented is an invaluable aid when tracking down a problem or planning a modification. Rather than having to search your memory for information on what you did a long time ago, you'll have the facts on hand. The best time to prepare your notes is as you're building, so take a few minutes at each step to record your progress.

When documenting your shack, include information such as the type, size and length of the primary wiring, as well as the value of circuit breakers or fuses. Keep track of your cables. Write down the pinouts of the various plugs and connectors joining your equipment, including microphone cables, keyer wiring and control circuitry. If a piece of equipment has

more than one possible hookup configuration (say, for example, high or low impedance for a microphone or 117 or 234 V for a transformer), note which connections you used as well as the ones you didn't. For multiconductor cables, make a list of the colors of the wires and their functions.

Documenting your antenna system is especially important. For towers, make and keep drawings of the entire installation. Include sketches with measurements of such things as the tower base and guy anchors. Write down your guy-wire lengths. If you break your guys into non-resonant lengths with insulators, note the lengths of the individual sections for each set of wires. Knowing what you have in the present installation will make repairing or upgrading the tower much easier in the future.

Make a list of the bolt sizes used for the tower, rotator, mast and antenna(s). List the wrench size required for all hardware. This way, you'll know which wrenches to take along for a specific job. For example, to remove your rotator for repair, you may need a 7/16-in wrench to remove the U-bolts securing the mast and a 1/2-in wrench for the bolts holding the rotator housing to the mounting plate. If you guess and take the wrong size, you'll have to make additional unnecessary trips up and down the tower. If you bring along all of your tools for a job requiring only one or two wrenches, you'll weigh yourself down and the climb will be harder than necessary.

If your diagram of the mast and antenna(s) includes the size of the mast and the spacing between antennas (if you have more than one on the same mast), you'll be better prepared to add or change antennas in the future. You'll be able to fabricate boom-to-mast clamps on the ground and hoist them up the tower with the confidence that you'll have to do the job only once — the hardware will fit perfectly. By knowing how much mast is sticking out of the top of the tower, you'll know, for example, whether or not you can replace an antenna that has a self-supporting boom with another requiring a specific number of feet of mast for a boom brace. If you know the distance between antennas, you'll be able to determine if an additional antenna on the mast is feasible. Having the measurements on hand takes the guesswork out of many jobs and saves unnecessary trips up and down the tower to make new measurements every time you want to make a change.

Cables and connectors are worth documenting as well. As you build your antenna system, note the length and type of each piece of feed line, rotator and control cable used. Document the type of connectors used. Be sure to write down the color code used for the rotator cable; if some day you disconnect the control box in the shack and don't have the codes in your notebook, you'll have to climb the tower to find out how they go. If you know the lengths of your cables and the types of

Fig. 36 — Solder-type DB-25 connector and prepared ribbon cable.

Fig. 37 — Crimp-type connector with prepared ribbon cable.

Fig. 38 — Many amateurs run their cables through an open double-hung window. The window should be sealed against the weather.

connectors used, it will be a great help in troubleshooting. You will be able to prepare test and/or replacement cables before leaving the ground.

Besides documenting the interconnections and hardware around your station, you should also keep track of the performance of your equipment. There are many different performance tests you can make, and what you do will depend on your

Fig. 39 — A window pane may be replaced with an acrylic sheet and then drilled to pass cables.

Fig. 40 — An ordinary dryer vent pipe will pass a large number of cables.

technical ability and the test equipment on hand. There are, however, some basic tests that almost every amateur can make. Each time you install a new antenna, measure the SWR at different points in the band and make a table or plot a curve. Later, if you suspect a problem, you'll be able to look in your records and compare your SWR with the original performance. You might also want to measure the loss of each piece of feed line before installation. Most feed line degrades with time, so again you'll have a benchmark to compare with if you have a problem later. This measurement is easy; just terminate the feed line with a dummy load, and compare the power measured at the transmitter end with that measured at the dummy load.

In your shack, you can measure the power output from your transmitter(s) and amplifier(s) on each band. These measurements will be helpful if you later

suspect you have a problem, such as your rig going out of alignment. They will also help you see when your tubes start to go soft. For receivers, it may be helpful to turn on the crystal calibrator and note the S-meter reading on various bands. The calibrator output is fairly constant, so future S-meter readings different from the original ones may indicate alignment or other problems. Of course, if you have access to a signal generator you can measure receiver performance for future reference.

As part of your station records, keep a maintenance log showing details of any repairs or modifications to your gear. For modifications, make a copy of the schematic and add in changes on the copy. You can scrape traces from a photocopy with a sharp knife and draw in the new lines and/or components. Also, write down the details and keep a copy of any literature

pertaining to it (a magazine article or manufacturer's update note, for example). If you do any before/after testing, note your results.

Keep a list of purchases of station equipment. Include the serial number, price paid, date of purchase, and name and address of the seller. If you purchased the gear new from a dealer, this information should appear on the invoice. These records will come in handy at resale time. It's also advisable to have this information for insurance purposes, should anything happen to your equipment.

Station documentation can be as formal or informal as you like. Some amateurs will keep a file drawer with folders for the various aspects of the station. Others will keep a three-ring notebook separated into several sections. If you keep the documentation simple, you will be more likely to do it, and good records are very helpful.

## Assembling Your Antenna System

The antenna system is one area where amateurs have considerable room for experimentation. No two antenna systems are alike, and the shape yours takes will depend on the amount of land available, your resources and your interests. Your antenna system might consist of a multiband dipole, or you might want to chase DX and work contests with monoband beams installed on individual towers. The antenna system is your chance to be creative.

The information presented here explains some of the methods used to put antennas into the air and keep them there. Information on antenna design is covered in Chapter 17, while antenna construction is presented in Chapter 33. The *ARRL*

*Antenna Book* is another good source of information on antenna theory and construction. This section assumes that you have an antenna in mind or assembled and are looking for ideas on how to support it.

### SUPPORTING WIRE ANTENNAS

The antenna can be supported at the ends by buildings, trees or anything you may be able to use. Later in this chapter, there is information on putting up poles and masts. A mast may be the real answer to holding up at least one end of the antenna. Many operators fasten one end of the antenna to the house, or to a short pole on the roof, and build a mast far enough away to permit using the desired antenna length. The

spot for the mast can be chosen so the antenna will be in the clear.

You can slope the antenna wire if your two supports aren't the same height. A sloping antenna usually will radiate best in the direction of the downslope. You can take advantage of this effect by deliberately sloping the wire to get a desired "best" direction.

### Trees as Antenna Supports

From the beginning of Amateur Radio, trees have been used widely for supporting wire antennas. Trees cost nothing, of course, and will often provide a means of supporting a wire antenna at considerable height. As an antenna support, however,

a tree is highly unstable in the presence of wind, unless the tree is a very large one and the antenna is suspended from a point well down on the tree trunk. As a result, the antenna must be constructed much more sturdily than would be necessary with stable supports. Even with rugged construction, it is unlikely that an antenna suspended from a tree, or between trees, will stand up indefinitely.

There are two general methods of securing a pulley to a tree. If the tree can be climbed safely to the desired level, a pulley can be wired to the trunk of the tree, as shown in Fig. 41. If, after passing the halyard through the pulley, both ends of the halyard are simply brought back down to ground along the trunk of the tree, there may be difficulty in bringing the antenna end of the halyard out where it will be clear of branches. To avoid this, one end of the halyard can be tied temporarily to the tree at the pulley level, while the remainder of the halyard is coiled up, and the coil thrown out horizontally from this level, in the direction in which the antenna will run. It may help to have the antenna end of the halyard weighted. Then, after attaching the antenna to the halyard, the other end is untied from the tree, passed through the pulley, and brought to ground along the tree trunk in as straight a line as possible. The halyard need be only long enough to reach the ground after the antenna has been hauled up, since additional rope can be tied

to the halyard when it becomes necessary to lower the antenna.

The other method consists of passing a line over the tree from ground level, and using this line to haul a pulley up into the tree and hold it there. Several ingenious methods have been used to accomplish this. The simplest method employs a weighted pilot line, such as fishing line or mason's chalk line. Grasping the line about 2 feet from the weight, the weight is swung back and forth, pendulum style, and then heaved with an underhand motion in the direction of the tree top. Several trials may be necessary to determine the optimum size of the weight for the line selected, the distance between the weight and the hand before throwing, and the point in the arc of the swing where the line is released. The weight, however, must be sufficiently large to ensure that it will carry the pilot line back to ground after passing over the tree. Flipping the end of the line up and down so as to put a traveling wave on the line often helps to induce the weight to drop down if the weight is marginal. The higher the tree, the lighter the weight and the pilot line must be. A glove should be worn on the throwing hand, because a line running swiftly through the bare hand can cause a severe burn.

If there is a clear line of sight between ground and a particularly desirable crotch in the tree, it may be possible to hit the crotch eventually after a sufficient number of tries. Otherwise, it is best to try to heave the pilot line completely over the tree, as close to the center line of the tree as possible. If it is necessary to retrieve the line and start over again, let the weighted end drop to the ground and pull the pilot line through the tree. If you pull the weight back through the tree, it may wrap the line around a small limb, making retrieval impossible.

Stretching the line out in a straight line on the ground before throwing may help to keep the line from snarling, but it places extra drag on the line, and the line may snag on obstructions overhanging the line when it is thrown. Another method is to make a stationary reel by driving eight nails, arranged in a circle, through a 1-inch board. After winding the line around the circle formed by the nails, the line should reel off readily when the weighted end of the line is thrown. The board should be tilted at approximately right angles to the path of the throw.

Other devices that have been used successfully to pass a pilot line over a tree are the bow and arrow with heavy thread tied to the arrow, and the short casting rod and spinning reel used by fishermen. Still another method that has been used where sufficient space is available is to fly a kite. After the kite has reached sufficient altitude, simply walk around the tree until the kite string lines up with the center of the tree. Then pay out string until the kite falls to the earth. This method has been used

Fig. 41 — Methods of counterweighting to minimize antenna movement. The method at A limits the fall of the counterweight should the antenna break. It also has a 2 to 1 mechanical advantage, as indicated. The method at B has the disadvantage that the point of support in the tree must be higher than the end of the antenna.

Fig. 42 — In connecting the halyard to the pilot line, a large knot that might snag in the crotch of a tree should be avoided, as shown.

Fig. 43 — A weighted line thrown over the antenna can be used to pull the antenna to one side to avoid overhanging obstructions, such as branches of trees in the path of the antenna, as the antenna is pulled up. When the obstruction has been cleared, the line can be removed by releasing one end.

successfully to pass a line over a patch of woods between two higher supports, which would have been impossible using any other method.

The pilot line can be used to pull successively heavier lines over the tree until one of adequate size to take the strain of the antenna has been reached. This line is then used to haul a pulley up into the tree after the antenna halyard has been threaded through the pulley. The line that holds the pulley must be capable of withstanding considerable chafing where it passes through the crotch, and at points where lower branches may rub against the standing part. For this reason, it may be advisable to use galvanized sash cord or stranded guy wire for raising the pulley.

Especially with larger sizes of line or cable, care must be taken when splicing the pilot line to the heavier line to use a splice that will minimize the chances that the splice cannot be coaxed through the tree crotch. One type of splice is shown in Fig. 42.

The crotch which the line first comes to rest in may not be sufficiently strong to stand up under the tension of the antenna. However, if the line has been passed over, or close to, the center line of the tree, it will usually break through the lighter crotches and finally come to rest in one sufficiently strong lower down on the tree.

Needless to say, any of the suggested

Fig. 44 — The cleat helps you avoid having to untie a knot that may have been weather-hardened.

Fig. 45 — Using a length of 2 x 3 as a support for a horizontal antenna. Lengths up to 20 feet can be used with a single set of guys arranged as shown.

methods should be used with due respect to persons or property in the immediate vicinity. A child's sponge-rubber ball (baseball size) makes a safe weight for heavy thread line or fishing line.

If the antenna wire becomes snagged in lower branches of the tree when the wire is pulled up, or if branches of other trees in the vicinity interfere with raising the antenna, a weighted line thrown over the antenna and slid along to the appropriate point is often helpful in pulling the antenna wire to one side to clear the interference as the antenna is being raised, as shown in Fig. 43.

### Wind Compensation

The movement of an antenna suspended

between supports that are not stable in wind can be reduced materially by the use of heavy springs, such as screen-door springs under tension, or by a counterweight at the end of one halyard, as shown in Fig. 41. The weight, which may be made up of junk-yard metal, window sash weights, or a galvanized pail filled with sand or stone, should be adjusted experimentally for best results under existing conditions. Fig. 44 shows a convenient way of fastening the counterweight to the halyard. It avoids the necessity for untying a knot in the halyard which may have hardened under tension and exposure to the weather.

### Man-Made Supports

In practice, a height of 30 to 60 feet is in the optimum region for any band above 7 MHz where the ionosphere plays a part.

You can get by with even less than 30 feet if you have to. However, nearly everyone can put an antenna at least 25 feet or so in the air. This height puts it in the class where, usually, at least one end can be supported by your house. The other end can be held up by another building (if you have permission to use it) far enough away, or by a tree, or if necessary by a pole you put up yourself. The pole doesn't have to be an elaborate structure, especially if it can be erected on top of something. A detached garage makes a good base. It should give you a start of 12 to 15 feet, and generally will have enough roof area to let you put guys on a simple wood pole that can be up to 20 feet tall. It is important to realize that antennas with horizontal polarity should be one-half wavelength or more above ground for best results in long-distance communications.

### Anchoring

Wire antennas are not heavy, and even when pulled up tight the strain can easily be supported by a husky screw eye or hook, if it can be sunk 1 1/2 or 2 inches into good solid wood. Screw eyes can be used similarly for anchoring guy wires from light poles up to 20 feet long. Often other anchorages for guy wires offer themselves; use anything that seems solid enough and which gives you the opportunity for wrapping the wire around a couple of times so it won't slip.

A length of 2 x 3 makes a good pole for heights up to 20 feet or so. It isn't heavy, but with three solidly anchored guys it will hold any wire antenna you may use with it. Fig. 45 shows a simple type of construction, using fittings that you can buy at a hardware store. The pulley and halyard make it possible to raise and lower the antenna easily. With the antenna up, only two guys are really necessary, placed 90 to 120 degrees apart back of the antenna, as shown at B and C. The third guy, A, can be part way down the pole so it will be out of the way of the pulley and halyard, and should pull off in about the same direction as the antenna. Its purpose is to hold the

Fig. 46 — This mast construction is suitable for heights up to 40 feet, for supporting a horizontal antenna. Pivoting the mast on the lower bolt, A, simplifies the job of raising and lowering.

pole up when the antenna is down.

The guys can simply be wrapped around the pole near the top. One is shown in the drawing. To keep them from slipping down they can be run through a screw eye as shown. This avoids putting any strain on the screw eye. Stranded steel wire available in hardware stores (a typical type has four strands of about the same diameter as no. 18 copper) has ample strength for guying a pole of this type. Guy wire also is available from radio supply houses.

Plastic clothesline can be used for the halyard. The plastic kind stands the weather better than ordinary cotton clothesline. If you do use cotton, get the type having a steel core; it has greater strength and lasting qualities. But whatever type you use, be sure to use enough. Remember that you need to be able to reach the free end of the halyard when the antenna is down!

### Simple Wooden Mast

If you have to set a mast on the ground, the structure shown in Fig. 46 is easy to build and erect. Three 20-foot lengths of 2 x 3 are used to make a mast 40 feet tall. It makes a sturdy support for a horizontal-wire antenna when properly guyed. The mast is pivoted at the base for ease in raising (and lowering, if necessary), the pivot being the lower carriage bolt (A) shown in the drawing.

The base is a length of 2 x 4 set solidly in the ground. The 2 x 4 should be buried to a depth of about 3 feet and should extend at least 3 feet above the ground level. Use a plumb line to make sure it is vertical

Fig. 47 — Pipe guy anchor. One-inch or 1½-inch iron pipe is satisfactory for a mast such as is shown in Fig. 46.

when setting it. Pack rocks around it before refilling the hole with dirt; this will make a solid foundation, which is helpful when the mast is being raised. After it is up and the guys are in place, the stress on the base is practically all straight down, so there is really no need for an elaborate footing.

The mast should be assembled on the ground (with the antenna halyard affixed; the method shown in Fig. 45 can be used for this) and fastened to the ground post with the lower carriage bolt. The guy wires, which should be made long enough to reach their anchorages while the mast is down, also should be attached. Push the mast straight up at the middle, letting it pivot on the bolt. When it gets up high enough, have an assistant slide a ladder under it to hold it. Keep working it up, moving the ladder down the mast as you go. Stop now and then to pull up on the guys. Keep the front guy short enough so the mast won't swing all the way over and come down on the other side, but leave it loose enough so it can't interfere as the mast goes up. When the mast approaches the vertical, pulling on the top guys will bring it up the rest of the way. Slip in the upper carriage bolt (B) and the mast will stand by itself (if the base is solid) while you adjust the lower set of guys. Don't give the top guys their final tightening until the antenna is up, as they must work against the pull of the antenna.

The guy wires should be anchored about 20 feet from the base of the mast, for a height of 40 feet. If shorter 2 × 3s are used so that the completed mast is less tall, this distance can be correspondingly reduced.

#### Insulating Guy Wires

Guy wires are like antenna wires — if their length happens to be near resonance at your operating frequency, they can pick up energy from the antenna field and re-radiate it. This may do no harm, but then again it might distort the radiation pattern you hope the antenna will give.

To circumvent this, guy wires are often "broken up" by inserting insulators at strategic points. The idea is to avoid letting any section of guy wire have a length that

is near resonance at any operating frequency or harmonic of it. Egg-type insulators are generally used as a safety measure. With these insulators the wires are looped around each other so that if the insulator breaks the guy wire will still hold.

General practice is to put an egg in each guy a foot or so from where it is attached to the pole or mast, and another a foot or so from the point where it is anchored. Whether any more are needed depends on the remaining length. In most cases it is sufficient to insert insulators in such a way that no section of the wire will have a length in feet that can be divided evenly by 16 or 22.

#### Guy Anchors

Trees or buildings at the right distance from the base of a mast can be used for anchoring guys. However, they don't always "just happen" to be present. In such a case a guy anchor can be sunk into the ground.

A 6-foot length of 1-inch iron pipe driven into the ground at about a 45-degree angle makes a good anchor. It should be driven toward the mast, with 12 to 18 inches protruding from the ground for fastening the wires. Fig. 47 shows the general idea, with a suggested way of fastening the guy so it can't slip off the anchor.

#### Weather Protection

A wooden mast or pole needs the same protection against weather as the exterior woodwork on a dwelling. New wood should be given three coats of a good paint made for outdoor use, with the first coat thinned so it sinks in well. Follow the directions on the paint container.

Masts made from several pieces of lumber, such as the one shown in Fig. 46, should have their individual parts painted separately before assembly. The heads of nails or screws should be sunk into the surface far enough so they can be puttied over. These, too, should be painted — after assembly. Hooks, screw eyes and similar hardware should likewise have a coat of paint to prevent rusting.

#### Other Types of Masts

Amateur ingenuity has conjured up all sorts of mast and tower designs over the years. It is possible, for example, to make a satisfactory pole, 40 feet or so high, out of lengths of metal down-spouting. Wooden lattice construction has long been a favorite for masts and towers. A number of such designs will be found in *The ARRL Antenna Book*, and new ones keep coming along regularly in *QST*. Then there are TV masts, built up in sections of metal tubing and provided with guy rings and other hardware — readily available and not at all costly. These can be run up to heights as great as 50 feet, with proper guying.

In fact, anything you can put up, and that will stay up, will be satisfactory. Never forget that you can't afford to take any chances with safety. A falling mast can

result in accidental injury, or even death, to anyone that happens to be in its path. The taller and heavier the mast, the more necessary it becomes to build in plenty of safety factor — in size of guy wire, type of anchorage, and in the strength and cross section of the materials used in the mast or tower itself.

## TOWERS

A mast is fine for supporting one end of a wire antenna, or a small vertical, or even a small VHF/UHF beam, but the right way to support an HF beam or a large VHF/UHF array is with a communications tower designed for this purpose. The information in this section is intended to help you choose the right type of tower for your needs, provide information on erecting the tower, and present some ideas on getting the antenna to the top.

Working on towers and antennas is dangerous, and possibly fatal, if you do not know what you are doing. Your tower and antenna can cause serious property damage and personal injury if any part of the installation should fail. Always use the highest quality materials in your system. Follow the manufacturer's specifications, paying close attention to base pier and guying details. Do not overload the tower. If you have any doubts about your ability to work on your tower and antennas safely, contact another amateur with experience in this area or seek professional assistance.

Information on antenna theory appears in Chapter 17. Practical antenna construction projects are presented in Chapter 33. Information on making the cables to connect your antennas, rotator cables and control lines appears earlier in this chapter. *The ARRL Antenna Book* is an excellent source of antenna information, and *QST* regularly features articles on antennas.

## TOOLS

Any mechanical job is easier if you have the right tools. Tower work is no exception. In addition to a good assortment of wrenches, screwdrivers and pliers, you will need some specialized tools to work safely and efficiently on a tower. You may already own some of these tools. Others will be purchased or borrowed. Do not start a job until you have assembled all of the necessary tools. Shortcuts or improvised tools can be fatal if you gamble and lose at 50 feet in the air.

#### Clothing

The clothing you wear when working on towers and antennas should be selected for maximum comfort and safety. Wear clothing that will keep you warm, yet allows complete freedom of movement. Long denim pants and long-sleeve shirts will protect you from scrapes and cuts. Wear work shoes with heavy soles, or better yet steel inserts in the soles, to give your feet the support they need to stand on a narrow tower rung.

Gloves are necessary for both the tower climber and all ground-crew members. Good quality leather gloves will protect hands from damage and keep them warm. They also offer protection and a better grip when you are handling rope.

Ground-crew members should have hard hats to protect them in case something falls from the tower. It is not uncommon for the tower climber to drop tools and hardware. A wrench dropped from 100 feet will bury itself several inches in soft ground; imagine what it might do to an unprotected skull.

### Safety Belt and Climbing Accessories

Any amateur with a tower *must* own a high-quality safety belt, such as the one shown in Fig. 48. Do not attempt to climb a tower, even a short distance, without a belt. The climbing belt is more than just a safety device for the experienced climber. It is a tool to free up both hands for work. The belt allows the climber to lean back away from the tower to reach bolts or connections. It also provides a solid surface to lean against to exert greater force when hoisting antennas into place.

A climber must trust his life to his safety belt. For this reason, nothing less than a professional-quality, commercially made, tested and approved safety belt is acceptable. Check the equipment suppliers list in Chapter 35 and the ads in *QST* for suppliers of climbing belts and accessories. Check your belt *before each use* for defects. If the belt or lanyard (tower strap) are cracked, frayed or worn in any way, destroy the damaged piece and replace it with a new one. You should never have to wonder if your belt will hold.

Fig. 48 — A good-quality safety belt is a requirement for working on a tower. The belt should contain large steel loop for the strap snap. Leather loops at the rear of the belt are handy for holding tools. (photo by K1WA)

Along with your climbing belt, you should seriously consider the purchase of some climbing accessories. A canvas bucket is a great help for carrying tools and hardware up the tower. Two buckets, a large one for carrying tools and a smaller one for hardware, make it easier to find things when needed. A few extra snap hooks like those on the ends of your belt lanyard are useful for attaching tool bags and equipment to the tower at convenient spots. These hooks are better than using rope with knots in many cases because they can be hooked and unhooked with one hand.

Gorilla hooks, shown in Fig. 49, are especially useful for ascending and descending the tower. They attach to the belt and are hooked to the tower on alternating rungs as the climber progresses. With these hooks, the climber is secured to the tower at all times. Gorilla hooks were specially designed for amateur climbers by Avatar Magnetics (see Chapter 35 suppliers list).

### Rope and Pulley

Every amateur who owns a tower should also own a good quality rope at least twice as long as the tower is tall. The rope is essential for safely erecting towers and installing antennas and cables. For most installations, a good quality ½-inch-diameter manila hemp rope will do the job, although a thicker rope is stronger and easier to handle. Some types of polypropylene rope are acceptable also; check the manufacturer's strength ratings. Nylon rope is not recommended because it tends to stretch and is difficult to fasten knots with.

Check your rope *before each use* for tearing or chafing. Do not attempt to use damaged rope; if it breaks with a tower section or antenna in mid-air, property damage and personal injury are likely results. If your rope should get wet, let it thoroughly air dry before putting it away.

A most-worthwhile purchase is a pulley like the one shown in Fig. 50. Use the right size pulley for your rope. Be sure that the pulley you purchase will not jam or bind as the rope passes through it.

### The Gin Pole

The gin pole, shown in Fig. 51, is a handy device for working with tower sections and masts. This gin pole is designed to clamp onto one leg of Rohn No. 25 or 45 tower. The tubing, which is about 12 feet long, has a pulley on one end. A rope is routed through the tubing and over the pulley. When the gin pole is attached to the tower and the tubing extended into place, the rope may be used to haul tower sections or the mast into place. Fig. 52 shows the basic process.

A gin pole can be expensive for an individual to buy, especially for a one-time tower installation. Often, local radio clubs own a gin pole for use by their members. Stores that sell tower sections to amateurs and commercial customers frequently will

Fig. 49 — Gorilla hooks are designed to keep the climber attached to the tower at all times when ascending and descending.

Fig. 50 — A good quality rope and pulley are a must for anyone working on towers and antennas. This pulley is encased in wood so the rope cannot jump out of the pulley wheel and jam.

Fig. 51 — A gin pole is a mechanical device that can be clamped to a tower leg to aid in the assembly of sections as well as the installation of the mast. The aluminum tubing extends through the clamp and may be slipped into position before the tubing clamp is tightened. A rope should be routed through the tubing and over the pulley mounted at the top.

rent erection fixtures. If you attempt to make your own gin pole, use materials heavy enough for the job. Provide a means for securely clamping the pole to the tower. There are many cases on record where homemade gin poles have failed, sending tower sections crashing down amidst the ground crew.

When you use a gin pole, make every effort to keep the load as vertical as possible. Although gin poles are strong, you are asking for trouble if you apply too much lateral force.

### SELECTING A TOWER

Probably the most important part of any Amateur Radio installation is the antenna

Fig. 52 — The assembly of tower sections is made simple when a gin pole is used to lift each one into position. Note that the safety belts of both climbers are fastened below the pole, thereby preventing the strap from slipping over the top section. (photo by K1WA)

system. It determines the effectiveness of the signal transmitted at a particular power level. In terms of dollar investment, the antenna provides double duty; while it can provide gain during transmitting periods (which can also be accomplished by increasing transmitter power), it has the same beneficial effect on received signals. Therefore, a tall support for a gain antenna that can be rotated is very desirable. This is especially true if DX contacts are of prime interest on the 20, 15 and 10-meter bands.

Of the two important features of an antenna system, height and antenna gain, height is usually considered the most important if the antenna is horizontally polarized. The typical amateur installation consists of a three-element triband beam (tribander) for 20, 15 and 10 meters mounted on a tower that may be as low as 25 or 30 feet, or as high as 65 or 70 feet. Some systems use large antennas on much taller towers.

The selection of a tower, its height and the type of antenna and rotator to be used all may seem like a complicated matter, particularly for the newcomer. These four aspects of an antenna system are interrelated, and one should consider the overall system before making any decisions as to a specific component. Perhaps the most important consideration for many amateurs is the effect of the antenna system on the surrounding environment. If plenty of space is available for a tower installation and there is little chance of the antenna irritating neighbors, the amateur is indeed fortunate. This amateur's limitations will be mostly financial. But for most, the size of the backyard, the effect of the system on the family members and neighbors, local ordinances, and the proximity of power lines and poles influence the overall selection of antenna components considerably.

The amateur must consider several practical limitations for installation:

1) A tower should never be installed in such a way that it could fall onto a neighbor's property.

2) The antenna must be located in such a position that *it cannot possibly tangle with power lines during normal operation*, or if a disastrous windstorm comes along.

3) Sufficient yard space must be available to position a guyed tower *properly*. The guy anchors should be between 60 and 80 percent of the tower height in distance from the base of the tower.

4) Provisions must be made to keep neighborhood children from climbing the support.

5) Local ordinances should be checked to determine if any legal restrictions are on record.

Other important considerations are:

6) The total dollar value to be invested.

7) The size and weight of the antenna desired.

8) The overall yearly climate.

9) Ability of the owner to climb a fixed tower.

The selection of a tower support is usually dictated more by circumstances than by desire.

Once a decision has been tentatively made, the next step is to write to the manufacturer (several are listed in Table 2) and request a specification sheet. Meanwhile, lay out any guy anchor points needed to ensure that they will fit on the assigned property. The specification sheet for the tower should give a wind-load capability; an antenna can then be selected that will

not overload it. If a tentative decision on the antenna type is made, a note to the antenna manufacturer giving the complete set of details for installation is not a bad idea. Be sure to give complete details of your plans, including all specifications of the antenna system planned. Remember, the manufacturer will not custom design a system directly for your needs, but may offer comments.

It is often very helpful to the novice tower installer to visit other local amateurs who have installed towers. Look over their hardware and ask questions. If possible, have a few local experienced amateurs look over your plans — before you commit yourself. They may be able to offer a great deal of help. If someone in your area is planning to install a tower and antenna system, be sure to offer your assistance. There is no substitute for experience when it comes to tower work, and your experience there may prove invaluable to you later.

#### The Tower

The most common variety of tower is the guyed tower made of stacked identical sections. The information in Fig. 53 is based on data taken from the Unarco-Rohn catalog. A list of tower manufacturers can be found in Table 2. Rohn calls for a maximum vertical separation between sets of guy wires of 35 feet for this series of tower. At A, the tower is 70 feet high, and there are two sets of evenly spaced guy wires. At B, the tower is 80 feet high, and there are three sets of evenly spaced guy wires. Exceeding the vertical spacing requirements could result in the tower buckling.

This may not seem like a reasonable possibility unless you understand the functioning of the guy wires. The guy wires restrain the tower against the force of the wind and translate the lateral force of the wind into a downward compression that forces the tower down onto the base. Normally, the manufacturers specify the initial tension in the guy wires. This is another force that is translated into the downward compression on the tower. If there are not enough guys and if they are not properly spaced, a heavy gust of wind may turn out to be the "straw that breaks the camel's back." Fig. 53C is an overhead view of a guyed tower. Manufacturers usually call for equal angular spacing between guys. If it is necessary to deviate from this spacing, you would be well advised to contact the engineering staff of the manufacturer or a civil engineer.

Some types of towers are not normally guyed — these are usually referred to as free-standing or self-supporting towers. The principles involved are the same regardless of the manufacturer's choice of names. The wind blowing against the side of the tower creates an overturning moment that would topple the tower if it were not for the anchoring at the base. Fig. 54 details the action and reaction involved. The tower

Fig. 53 — Diagram depicting proper method of installation of a typical guyed tower.

Fig. 54 — Diagram of typical free-standing (unguyed) tower. Arrows indicate the directions of the forces acting upon the structure. See text for discussion.

Fig. 55 — Two examples of "crank-up" towers.

is restrained by the base. As the wind blows against one side of the tower, the opposite side is compressed downward much as in the guyed-type setup. Because there are no guys to restrain the top, the side that the wind is blowing against is simultaneously being pulled up (uplift). The force of the wind is creating a moment that tends to pivot about a point in the base of the tower. The base of the guyed tower simply must hold the tower up, but the base of the free-standing tower must simultaneously hold one side of the tower up and the other side down! It should not be surprising that manufacturers often call for a great deal more concrete in the base of free-standing towers than they do in the base of guyed towers.

Fig. 55 shows two variations of another popular type of tower, the crank-up: In

regular guyed or free-standing towers, each section is bolted atop the next lower section. The height of the tower is the sum of the heights of the sections (minus any overlap). Not so with the crank-up towers. The outer diameter of each section is smaller than the inner diameter of the next lower section. Instead of bolting together, the sections are attached with a complex set of cables and pulleys. The overall height of the tower is adjusted by using the pulleys and cables to "telescope" the sections together or apart.

Depending on the design, the manufacturer may or may not require guy wires. The primary advantage of the crank-up tower is that the owner must do the antenna work near the ground. A second advantage is that the tower can be kept retracted except during use, which reduces the guying

Fig. 56 — Fold-over or tilting base. There are several different variations of hinged sections permitting widely different types of installation. Great care should be exercised when raising or lowering a tilting tower.

Fig. 57 — Another example of a concrete base (Tri-Ex LM-470).

needs (presumably, you would not try to extend the tower and use it during periods of high winds). The disadvantages include mechanical complexity and (usually) cost. It is extremely dangerous to climb on a crank-up tower, even if it is extended only a small amount.

Some towers have another convenience feature — a hinged section that permits the owner to fold over all or a portion of the tower. The primary benefit is in allowing antenna work to be done closer to ground level without the necessity of removing the antenna and lowering it. Fig. 56 shows a hinged base; of course, the hinged section can be designed for portions of the tower other than the base. Also, a hinged feature can be added to a crank-up tower.

Misuse of hinged sections during tower erections is a common problem among

radio amateurs. Unfortunately, these episodes often end in accidents. If you do not have a good grasp of the fundamentals of physics, it might be wise to avoid hinged towers (or to consult an expert). It is often far easier (and safer) to erect a regular guyed tower or self-supporting tower with gin pole and climbing belt than it is to try to “walk up” an unwieldy hinged tower.

### The Base

Each manufacturer will provide customers with detailed plans for properly constructing the base. Fig. 57 is an example of one such plan. This plan calls for a hole that is 3.5 × 3.5 × 6.0 feet. Steel reinforcement bars are lashed together and placed in the hole. The bars are positioned such that they will be completely embedded in the concrete, yet will not contact any metallic object in the base itself. This is done to minimize the possibility of a direct discharge path for lightning through the base. Should such a discharge occur, the concrete base would likely explode and bring about the collapse of the tower.

A strong wooden form is constructed around the top of the hole. The hole and the wooden form are filled with concrete so that the resultant block will be 4 inches above grade. The anchor bolts are embedded in the concrete before it hardens. Usually it's easier to ensure that the base is level and properly aligned by attaching the mounting base and the first section of the tower to the concrete anchor bolts. Each manufacturer will provide specific detailed instructions for the proper mounting procedure. Fig. 58 provides a slightly different design for a tower base.

The one assumption so far is that you have normal soil. “Normal soil” is a mixture of clay, loam, sand and small rocks. A technical discussion is beyond the scope of this book, but you may want to adopt more conservative design parameters for your base (usually, more concrete) if your soil is sandy, swampy or extremely rocky. If you have any doubts about your soil, contact your local agricultural extension office and ask for a more technical description of your soil. Once you have that information, contact the engineering department of your tower manufacturer or a civil engineer.

### Tower Installation

The installation of a tower is not difficult when the proper techniques are known. A guyed tower, in particular, is not hard to erect since each of the individual sections are relatively light in weight and can be handled with only a few helpers and some good-quality rope. A gin pole is a handy device for working with tower sections.

One of the most important aspects of any tower-installation project is the safety of all persons involved. Helpers should always stand clear of the tower base to prevent being hit by a dropped tool or hardware. When two people are climbing the tower,

one should climb into position before the other begins climbing. The same procedure is required for climbing down a tower after the job is completed. The purpose is to have the nonclimbing person stand relatively still so as not to drop any tools or objects on the climbing person, or unintentionally obstruct his movements. When two persons are working on top of a tower, only one should change position (unbelt and move) at a time.

### Attaching Guy Wires

In typical Amateur Radio installations a guy wire may experience “pulls” in excess of 1000 pounds. Under such circumstances, you do not merely twist the wires together and expect them to hold. Fig. 59 depicts the traditional method for fixing the end of a

Fig. 58 — Plans for installing concrete base for Wilson ST-77B. Although the instructions and dimensions will vary from one tower to the next, this is representative of the type of concrete base specified by most manufacturers.

Fig. 59 — Traditional method of securing the end of a guy wire.

Fig. 60 — Alternative method for attaching guy wires using dead ends. The dead end on the right is completely assembled (the end of the guy wire was left extending from the grip for illustrative purposes). On the left, one side of the dead end has been partially attached to the guy wire. In front, a thimble for use where a sharp bend might cause the guy wire or dead end to break.

piece of guy wire. A thimble is used to prevent the wire from breaking because of a sharp bend at the point of intersection. Three cable clamps follow to hold the wire securely. As a final backup measure, the individual strands of the free end are unraveled and wrapped around the guy wire. It is a lot of work, but it is necessary to ensure a firm connection.

Fig. 60 shows the use of a device that replaces the clamps and twisted strands of wire. These devices are known as dead ends. They are far more convenient to use than are clamps. You must cut the guy wire to the proper length. The dead end is installed into whatever the guy wire is being attached to (use a thimble, if needed). One side of the dead end is then wrapped around the guy wire. The other side of the dead end follows. The savings in time and trouble more than make up for the slightly higher cost.

Guy wire comes in different sizes, strengths and types. Typically, 3/16-inch EHS (extra high strength) guy wire with a breaking strength of 3990 pounds will be adequate for the moderate tower installation found at most Amateur Radio stations. Some amateurs prefer to use 5/32-in "aircraft cable." Although this cable is somewhat more flexible than 3/16-inch EHS, it is only about 70% as strong. It is recommended that you stay with standard guy wire and that you use nothing smaller than 3/16-inch EHS.

Fig. 61 shows two different methods for attaching guy wires to towers. At A, the guy wire is simply looped around the tower leg and terminated in the usual manner. At B, a "torque bracket" has been added. There probably isn't much difference in performance for wind forces that are tending to push the tower over. If you happen to have more projected area (antennas, feed lines, etc.) on one side of the tower than the other, or a long-boom Yagi at the top, then the force of the wind will cause the tower to tend to twist into the ground. The torque bracket will be far more effective in resisting this twisting motion than will the simpler installation. If you have any doubts about how much twisting a tower

can do, go outside and carefully watch one in a windstorm. The trade-off, of course, is in terms of initial cost.

There are two main types of anchors used for guy wires. Fig. 62A depicts an earth screw. It usually measures 4 to 6 feet long. The screw blade at the bottom typically measures 6 to 8 inches in diameter. Fig. 62B illustrates two people installing the anchor. The shaft is tilted such that it will be in line with the guy wires. Earth screws are suitable for use in "normal" soil where permitted by local building codes.

The alternative to earth screws is the concrete block anchor. Fig. 62C shows the installation of this type of anchor; it is suitable for any soil condition, with the possible exception of a bed of lava rock or coral. Consult the instructions from the manufacturer for the precise method of installation.

Guy wires can receive and reradiate RF energy. Reradiation can, in turn, distort the pattern of a directional array and can sometimes contribute to RFI. These conditions are aggravated when one or more guy wires is resonant at the operating frequency or one of its harmonics. To avoid resonance, the guy wires should be broken up into nonresonant lengths with egg strain insulators. Fig. 63 shows wire lengths that fall within 10 percent of half-wave resonance in the popular HF bands. These lengths should be avoided.

Turnbuckles and associated hardware are used to attach guy wires to anchors and to provide a convenient method of adjusting tension on the guy wires. Fig. 64A shows a turnbuckle of a single guy wire attached to the eye of the anchor. Turnbuckles are usually fitted with either two eyes or one eye, and one jaw. The eyes are the oval ends, while the jaws are U-shaped with a bolt through the tips.

Fig. 64B depicts two turnbuckles attached to the eye of an anchor. The procedure for installation is to remove the bolt from the jaw, pass the jaw over the eye of the anchor and reinstall the bolt through the jaw, through the eye of the anchor, and through the other side of the jaw. For two or more guys attached to one anchor, it is

Fig. 61 — Two methods of attaching guy wires to tower. See text for discussion.

Fig. 62 — Two standard types of guy anchors. The earth screw shown at A is easy to install and widely available, but it may not be suitable for use with abnormal soil. The concrete anchor is more difficult to install properly, but it is suitable for use with a wide variety of soil conditions and will satisfy most building code requirements.

recommended that you install an equalizer plate (Fig. 64C). In addition to providing a convenient point to attach the turnbuckles, the plate will pivot slightly and tend to equalize the tension on the guy wires. Once the installation is complete, a safety wire should be passed through the turnbuckles in a "figure-eight" fashion to prevent the turnbuckle from working loose.

### The Tower Shield

A tower can be legally classified as an "attractive nuisance" that could cause injuries unless some precautions are taken. The tower shield should eliminate the worry.

Generally, the "attractive nuisance" doctrine is based on the theory that one who maintains upon his premises an agency or condition that is dangerous to children of tender years by reason of their inability

Fig. 63 — Guy wire resonant lengths. The solid lines opposite the band designations indicate that the corresponding ungrounded length is a half wavelength or an integral multiple thereof. Grounded wires will exhibit resonance at odd multiples of a quarter wavelength. Ideal guy wire lengths are 0 to 14 ft, 18 to 20 ft, 24 to 29 ft, 39 to 40 ft and 57 to 58 ft. This chart was prepared by Jerry Hall, K1TD.

Fig. 64 — Variety of means available for attaching guy wires and turnbuckles to anchors.

Fig. 65 — Z-bracket component pieces.

Fig. 66 — Assembly of the Z bracket.

to appreciate danger and which may reasonably be expected to attract children to the premises, is under a duty to exercise reasonable care to protect them against dangers of the attraction.

The tower shield is simply composed of panels that enclose the tower and make climbing practically impossible. These panels are 5 feet in height and are wide enough to fit snugly between the tower legs and flat against the rungs. A height of 5 feet is sufficient in most every case. The panels are constructed from 18-gauge galvanized sheet metal obtained and cut to

proper dimensions from a local sheet-metal shop. A lighter gauge could probably be used, but the extra physical weight of the heavier gauge is an advantage if no additional means of securing the panels to the tower rungs are used. The three types of metals used for the components of the shield are supposedly rust proof and nonreactive. The panels are galvanized sheet steel, the brackets aluminum, and the screws and nuts are brass. The tower shield

consists of three panels, one for each of the three sides, supported by two brackets. These brackets are constructed from 6-inch pieces of thin aluminum angle stock. Two of these pieces are bolted together to form a Z bracket (see Figs. 65, 66 and 67). The Z brackets are bolted together with binding-head brass machine screws.

The panels are laid flat for measuring, marking and drilling. The first measurement is from the top of the upper mounting

Fig. 67 — Installation of the shield on a tower rung.

Fig. 68 — Removable handle construction.

rung on the tower to the top of the bottom rung. These mounting rungs are selected to position the panel on the tower. This distance from rung to rung is then marked on the panel. Using the same size brass screws and nuts, the top vertical portion of each Z bracket is bolted to the panel. The mounting-screw holes are drilled about 1 inch from the end of the Z brackets so that an offset clearance occurs between the Z-bracket binding-screw holes and the panel-bracket mounting-screw holes. The panel holes are drilled to match the Z-bracket holes.

The panels are held on the tower by their own weight. They are not easy to grasp because they fit snugly between the tower legs. If the need exists for added safety against deliberate removal of the panels, this can be accomplished by means of tie wires. A small hole can be drilled in the panel just above, just below, and in the

center of each Z bracket. Run a piece of heavy galvanized wire through the top hole, around the Z bracket, and then back through the hole just below the Z bracket. Twist together the two ends of the wire. One tie wire should be sufficient for each panel, but use two if desired.

The completed panels are rather bulky and difficult to handle. A feature that is useful if the panels have to be removed often for tower climbing or accessibility is a pair of removable handles. The removable handles can be constructed from one threaded rod and eight nuts (see Fig. 68). The two pairs of handle holes were drilled in the panels a few inches below the top Z bracket and several inches above the bottom Z bracket. For panel placement or removal, the handles are hooked in these holes in the panels. The hook, on the top of the handle, fits into the top hole of each pair of the handle holes. The handle is op-

Fig. 69 — Installed tower shield. Note the holes for using the handles.

tional, but for the effort required it certainly makes removal and replacement much safer and easier.

The installed tower shield can be seen in Fig. 69. This relatively simple device could prevent an accident.

## ANTENNA INSTALLATION

All antenna installations are different in some respects. Therefore, thorough planning is the most important first step in installing any antenna. At the beginning, before anyone climbs the tower, the whole process should be thought through. The procedure should be discussed to be sure each crew member understands what is to be done. Plan how to work out all bugs. Consider what tools and parts must be assembled and what items must be taken up the tower. Extra trips up and down the tower can be avoided by using forethought.

Getting ready to raise a beam requires planning. Done properly, the actual work of getting the antenna into position can be done quite easily with only one person at the top of the tower. The trick is to let the ground crew do all the work and leave the person on the tower free to guide the antenna into position.

Before the antenna can be hoisted into position, the tower and the area around it must be prepared. The ground crew should clear the area around the base while someone climbs the tower to remove any wire antennas or other objects that might get in the way. The first person to climb the tower should also rig the rope and pulley that will

Fig. 70 — Installing antennas on free-standing towers is relatively simple. At A, the pulley is rigged to the mast about 3 feet above the antenna mounting point. A snatch block at the tower base is used so the ground crew can pull horizontally, while keeping the strain on the tower in the vertical plane. The Yagi is suspended in a rope sling at the tower base. The ground crew pulls the antenna up (B), and the antenna will remain parallel to the ground if rigged properly. When the antenna reaches the tower top, the tower climber simply bolts it into place (C).

be used to raise the antenna. The time to prepare the tower is before the antenna leaves the ground, not after it becomes hopelessly entwined with your 80-meter dipole.

### Raising the Antenna

If you have a free-standing or crank-up tower, the task of actually getting the antenna from the ground to the tower top is simple. Rig a pulley to the mast as shown in Fig. 70. The pulley should be attached about 2 to 3 feet above the point where the antenna will bolt to the mast. If the antenna is heavy, it is advisable to rig a second pulley, or "snatch block," at the tower base. This arrangement allows the ground crew to use their entire body weight when pulling, rather than just the strength in their arms, making for a smoother and easier installation. The snatch block also keeps the load on the tower vertical, rather than lateral. Although many towers can take some lateral strain, it is better to be safe than sorry.

A properly designed and constructed antenna attaches to the mast at the balance point on the boom. If you rig a sling around the boom as shown in Fig. 70, you should be able to lift the antenna horizontally from the ground to the tower top. Be sure to rig the rope so that it does not

obstruct the boom-to-mast bolt holes. Do not rig the rope so that it will come between the boom-to-mast plate and the mast. Test your rigging by lifting the beam a few feet above the ground. If it tilts in any direction, let it back down and rig it again. It should be possible to balance the antenna in the horizontal plane.

When the beam is balanced and safely rigged, the ground crew starts pulling the antenna up the tower. In some installations, it will be possible to bring the antenna to the top of the tower without anyone leaving the ground. In most, however, the tower climber will have to follow the antenna up the tower to keep it from getting caught. When the antenna reaches the tower top, the climber simply has to bolt it into place.

### Avoiding Guy Wires

Although the same basic methods of installing a Yagi apply to any tower, guyed towers pose a special problem. Steps must be taken to avoid snagging the antenna on the guy wires. Let's consider, therefore, some ways in which this difficulty can be circumvented. With proper precautions, even large antennas can be pulled to the top of a tower, even if the mast is guyed at several levels.

Sometimes one of the top guys can pro-

vide a track to support the antenna as it is pulled upward. Insulators in the guys, however, may offer obstructions that could cause the beam to get hung up. A better track made with rope is an alternative, provided there is sufficient rope available. One end of the rope is secured outside the guy anchors. The other end is passed over the top of the tower and back down to an anchor near the first anchor. So arranged, the rope forms a narrow V track strung outside the guy wires. Once the V track is secured, the antenna may simply be pulled up the track.

Another method is to tie a rope to the back of the antenna (but within reach of the center). The ground crews then pull the antenna out away from the guys as the antenna is raised. With this method, some crew members are pulling up the antenna to raise it while others are pulling down and out to have the beam clear the guys. Obviously, the opposing crews must be coordinated or they can literally tear the antenna apart. The beam is especially vulnerable when it begins to tip into the horizontal position. If the crew pulling out and down continues to pull against the antenna, the boom can be broken. Another problem with this approach is that the antenna may rotate on the axis of the boom as it is raised. To prevent such rotation, long

Fig. 71 — The PVRC mount, boom-to-mast plate, mast and rotator ready to go. The mast and rotator are installed first.

lengths of twine may be tied to an element, one piece on each side of the boom. Ground personnel may then use these to stabilize the antenna. Where this is done, provision should be made for untying the twine once the antenna is in place.

A third method is to tie the halyard to the center of the antenna. A crew member, wearing a safety belt, walks the antenna up the tower as the crew on the ground raises it. Because the halyard is tied at the center balance point, the man on the tower can rotate the elements around the guys. A tag line can be tied to the bottom end of the boom so that a man on the ground can help move the antenna around the guys. The tag line must be removed while the antenna is still vertical and you can reach it.

## THE PVRC MOUNT

The above methods may not be satisfactory for large arrays on guyed towers. The best way to handle large Yagis is to assemble them on top of the tower. The way to do that is by using the "PVRC mount." Many members of the Potomac Valley Radio Club have used this method successfully to install their large antennas. Simple and ingenious, the idea involves offsetting the boom from the mast to permit the boom to tilt  $360^\circ$  and rotate axially  $360^\circ$ . This permits the entire length of the boom to be brought alongside the tower, allowing the elements to be attached one by one.

Fig. 72 — Close-up of the PVRC mount. Two of the four locking pins (bolts) may be seen at the midline of the left hand vertical plate. The other two pins are located along the axis of the short pipe section; the head of the right-hand bolt blends in with the U-bolt lock nut to the rear.

See Figs. 71 through 75. The mount itself consists of a short length of pipe of the same (or greater) diameter as the rotating mast, a steel plate and the hardware to hold it all together. The plate is drilled for eight U-bolts: four to attach the plate to the pipe, and four to attach the pipe to the antenna boom-to-mast plate. Additionally, four pinning bolts are used to ensure that the antenna will end up level and parallel to the ground. Two pinning bolts pass through the mast, two through the horizontal pipe. When the horizontal pipe pinning bolts are removed and the U-bolts are loosened, the boom-to-mast plate can be tilted  $360^\circ$ , allowing either half of the boom to come alongside the tower.

After all critical dimensions have been marked, the antenna elements are removed from the boom. Once the rotator and mast have been installed on the tower, a gin pole is used to bring the adapter plate and pipe to the top of the tower. There, the "top crew" unpins the horizontal pipe and tilts the antenna boom-to-mast plate to place it in the vertical plane. The boom is attached to the boom-to-mast plate at the balance point of the assembled antenna. It is important that the boom be rotated axially so the bottom side of the boom is closest to the tower. This will ensure that the antenna elements will be parallel to the side of the tower during installation, allowing the boom to be tilted without the elements striking the tower.

During installation it may be necessary to remove one guy wire temporarily to allow for tilting of the boom. As a safety precaution, a temporary guy should be mounted to the same leg of the tower just low enough so that the antenna will not hit it.

The elements are assembled on the boom starting with those closest to the center of the boom, working out alternately to the

farthest director and reflector. This procedure must be followed. If all the elements are put first on one half of the boom, it will be dangerous (if not impossible) to put on the remaining elements. By starting at the middle and working outward the antenna weight will never be so far removed from the balance point that tilting of the boom becomes impossible.

When the last element is attached, the boom is brought parallel to the ground, the horizontal pipe is pinned and the U-bolts tightened. Now, all the antenna elements are positioned vertically. Next, loosen the U-bolts that hold the boom and rotate the boom axially  $90^\circ$ , bringing the elements parallel to the ground. Then tighten the boom U-bolts and double-check all the hardware.

Many long-boom Yagis employ a truss to prevent boom sag. With the type of mount just described the truss must be attached to a pipe that is independent of the rotating mast. A short length of pipe is attached to the boom as close as possible to the balance point. The truss will now move along with the boom whenever the boom is tilted or twisted.

## ROTATOR SYSTEMS

There are not many choices when it comes to antenna rotators for the amateur antenna system. Choosing the right rotator is very important if trouble-free operation is desired. There are basically four grades of rotators available to the amateur. The lightest-duty rotator is the TV type, typically used to turn TV antennas. These rotators will handle, without much difficulty, a small three-element tribander (20-, 15- and 10-meter) array or a single 15- or 10-meter monoband three-element antenna.

The important consideration with a TV rotator is that it lacks braking or holding capability. High winds will turn the rotator

Fig. 73 — Working at the 70-foot level. A gin pole makes pulling up and mounting the boom to the boom-to-mast plate a safe and easy procedure.

Fig. 74 — Mounting the last element prior to positioning the boom in a horizontal plane.

motor via the gear train in a reverse fashion, sometimes resulting in broken gears. The next grade up from the TV class of rotator usually includes a braking arrangement whereby the antenna is held in place when power is not applied to the

rotator. Generally speaking, the brake will prevent gear damage on windy days. If adequate precautions are taken, this group of rotators is capable of holding and turning stacked monoband arrays, or up to a five-element 20-meter system. The next step up in strength is more expensive. This class of rotator will turn just about anything the most demanding amateur might want to install.

A description of antenna rotators would not be complete without the mention of the prop-pitch class. This rotator system consists of a surplus aircraft propeller-blade pitch motor coupled to an indicator system as well as a power supply. There are installation problems, however. It has been said that a prop-pitch rotator system, properly installed, is capable of turning a house. This is no doubt true! Perhaps in the same class as the prop-pitch motor but with somewhat less capability is the electric motor of the type used for opening garage doors. These have been used successfully in turning large arrays.

Proper installation of the antenna rotator can provide many years of trouble-free service; sloppy installation can cause problems such as a burned-out motor, slippage, binding and casting breakage. Most rotators are capable of accepting mast sizes of different diameters, and suitable precautions must be taken to shim an undersized mast to ensure dead-center rotation. It is very desirable to mount the rotator inside and as far below the top of the tower as possible. The mast will absorb the torque developed by the antenna during high winds, as well as during starting and stopping. A mast length of 10 feet or more between the rotator and the antenna will add greatly to the longevity of the entire system. Some amateurs have used a long mast from the top to the base of the tower. Installation and service can be accomplished at ground level. Another benefit of mounting the rotator 10 or more feet below the antenna is that any misalignment among the rotator, mast and the top of the tower is less significant. A tube at the top of the tower through which the mast protrudes will almost completely eliminate lateral forces on the rotator casting. All the rotator need do is support the downward weight of the antenna system and turn the array. While the normal weight of the antenna and the mast is usually not more than a couple of hundred pounds, even with a large system, one can ease this strain on the rotator by installing a thrust bearing at the top of the tower. The bearing is then the component that holds all the weight, and the rotator need perform only the rotating task.

A problem often encountered in the

Fig. 75 — The mast-to-pipe U-bolts are loosened and the boom is turned to a horizontal position. This puts the elements in a vertical plane. Then the pipe U-bolts are tightened and pinning bolts secured. The boom U-bolts are then loosened and the boom turned axially 90°.

amateur installation is that of misalignment between the direction indication of the rotator control box and the heading of the antenna. This is caused by mechanical slippage in the system caused by loose bolts or antenna boom-to-mast hardware. Many texts suggest that the boom be pinned to the mast with a heavy-duty bolt and, likewise, the rotator be pinned to the mast. There is a trade-off here. The amateur might not like to climb the tower and straighten out the assembly after each heavy windstorm. However, if there is sufficient wind to cause slippage in the couplings, the wind could break a casting. The slippage will act as a clutch release, which may prevent serious damage.

#### Completing the Installation

Once you've completed the tower, mast, antenna and rotator installation, verify that everything works. After you've done this, it is important to put on the finishing touches. Waterproof any coaxial cable connections and control lead connections. Use plenty of electrical tape, some heat-shrink tubing, or putty. Tape the cable along the antenna boom and down the mast. At the tower top, leave a loop large enough that the antenna can turn 360 degrees without binding the coaxial cable. Then secure any cables to the tower leg all the way to the ground. Cables that flap in the wind may be damaged under stress.

#### Maintenance

It's a good idea to inspect your tower and antenna system several times during the year. Make a checklist and run through it from top to bottom. Look for loose or missing hardware, rust, structural defects and worn cables. Periodically check the tension of your guy wires and adjust them if necessary. Catch problems before they become serious.

# Mobile and Portable Stations

A major justification for the existence of Amateur Radio in the USA is to provide a pool of experienced operators in time of national or community need. When the call for emergency communications is voiced by cities, towns, counties, states or the federal government, mobile and portable radio equipment is pressed into service where needed. Aside from the occasional disaster and emergency type of communications, a great deal of pleasure and challenge can reward the amateur when operating portable or mobile under normal conditions.

Most mobile operation is carried out today by means of narrow-band FM and repeaters. The major repeater frequencies are in the 146, 220 and 440-MHz bands. It is expected that this reliable service mode will soon include widespread occupancy of the 1240-MHz band and higher.

Mobile HF-band operation still appeals to numerous amateurs because it eliminates the constrictions imposed by VHF and UHF repeaters, their operators and their normal coverage contours. When operating mobile on SSB or CW with HF transceivers, worldwide contacts are possible for those who enjoy that style of communication.

## MOBILE STATIONS

Layout of a mobile station is considerably easier than that of a fixed station. In most vehicles, space is limited so there are only one or two possible spots for locating the equipment. Whenever possible, it should be positioned so that the operator can reach the front-panel controls without compromising the ability to operate the automobile safely. Driving safely is *always* the first priority; operating radio equipment is secondary.

While most mobile operation is done at low power levels, such as 10 watts from a VHF FM transceiver, high-power mobile operation is entirely practical from the 13.6-V dc battery system. There are many VHF power amplifiers on the market today at power levels up to 150 watts that require 13.6-V dc. Also, many HF rigs in the 100-watt-output class will operate directly from the automobile power system. Dynamotors, vibrator packs and dc-to-dc converters are things of the past, making mobile operation much more attractive.

If the amateur transceiver or amplifier requires more than a few amperes at 13.6 volts, it is best to run a heavy cable directly to the automobile battery. Few automobile electrical systems are set up to allow you to safely draw the 20 amperes required for a 150-watt transmitter from the accessory connection on the fuse panel. Consult the wire table in Chapter 35 for the safe size wire for your installation. Keep in mind that the larger the wire, the lower the voltage drop under load; a larger conductor will help you to get the most from your

equipment. Adequately fuse your power cable. Automobile fires are costly and dangerous.

A variety of mobile antennas are available. Chapter 33 of this Handbook contains information on building and using mobile antennas for HF and VHF.

## Electrical-Noise Elimination

One of the most significant deterrents to effective signal reception during mobile or portable operation is electrical impulse noise from the automotive ignition system. The problem also arises during the use of gasoline-powered portable ac generators. This form of interference can completely mask a weak signal, thus rendering the station ineffective. Most electrical noise can be eliminated by taking logical steps toward suppressing it. The first step is to clean up the noise source itself, then utilize the receiver's built-in noise-reducing circuit as a last measure to knock down any noise pulses from passing cars, or from other man-made sources.

## Spark-Plug Noise

Most vehicles manufactured prior to 1975 were equipped with simple Kettering inductive-discharge ignition systems. A variety of noise-suppression methods were devised for these systems, including resistor spark plugs, clip-on suppressors, resistive high-voltage cable and even complete shielding. Resistive high-voltage cable and resistor plugs provide the greatest noise reduction for the least expense and effort. While almost all vehicles produced after 1960 had resistance cable as standard equipment, such cable develops microscopic cracks in the insulation and segmentation of the conductor after a few years of service. These defects can defeat the suppression ability of the cable before the engine performance degrades noticeably. Two years is a reasonable replacement interval for spark-plug cable. Earlier editions of this *Handbook* described complete shielding methods for inductive-discharge ignitions.

Some late-model automobiles employ sophisticated high-energy electronic ignition systems in an attempt to reduce exhaust pollution and increase fuel mileage. With increased sophistication comes greater sensitivity to modification — solutions to RFI caused by older Kettering systems cannot be uniformly applied to the modern electronic ignitions.

Such fixes may be ineffective at best, and at worst may impair the engine performance. One should thoroughly understand an ignition system before attempting to modify it. One of the significant features of capacitive discharge systems, for example, is extremely rapid voltage rise, which combats misfire caused by fouled spark plugs. Rapid voltage rise depends on a low

Fig. 76 — This may represent the ultimate in portable VHF operation. The aggregate antenna gain represented by this setup could be very effective in time of emergency. This installation was built and operated by N6NB. The antenna shown is effective also for EME work.

Fig. 77 — Field Day is many things to many people, but everyone who participates does so away from commercial power. These gents, members of the Murgas ARC of Wilkes-Barre, Pennsylvania, hoisted a 15-meter beam atop a truck for their 1981 effort. (photo by Mike Benish, K3SAE)

RC time constant presented to the output transformer. For this reason, high-voltage suppression cable designed for capacitive-discharge systems is wound with monel wire. It exhibits a distributed resistance of only about 600 ohms per foot, as contrasted with 10 kΩ per foot for carbon-center cable used with inductive-discharge systems. Increasing the RC product by shielding or installing improper spark-plug cable could seriously compromise the capacitive-discharge circuit operation.

Ferrite beads represent a possible means

for RFI reduction in newer vehicles. Both primary and secondary ignition leads are candidates for beads. Install them liberally, then load test the engine for adequate spark energy.

The plane sheet metal surfaces and cylindrical members such as exhaust pipes often exhibit resonance in one of the amateur bands. Such resonances encourage reradiation of spark impulse energy. Bonding these structural members with heavy braid can reduce the level of spark noise inside the vehicle and out. Other types of noise to be described later can also be helped by bonding. Here are the main areas to bond.

- (1) Engine to frame; (2) air cleaner to engine block; (3) exhaust lines to frame; (4) battery ground terminal to frame; (5) hood to fire wall; (6) steering column to frame; (7) bumpers to frame; and (8) trunk lid to frame.

On the whole, modern automobiles are cleaner from an RFI standpoint than those of 20 years ago. The interference problem, however, at least at VHF and UHF, persists because present-day receivers are about 10 dB more sensitive than their predecessors.

### Charging-System Noise

Noise from the vehicular battery-charging circuit can interfere with both transmission and reception of radio signals. The charging system of a modern automobile consists of a belt-driven, three-phase alternator and a solid-state voltage regulator. Solid-state regulators are a great improvement over the electromechanical vibrating contact units of earlier times. Interference from the charging system can affect a receiver in two ways: RF radiation can be picked up by the antenna, and noise can be conducted directly into the circuits via the power cable. "Alternator whine" is a common form of conducted interference. It has the greatest effect on VHF FM communications, because synthesized carrier generators and local oscillators are easily frequency modulated by power supply voltage fluctuations. The alternator ripple is most noticeable when transmitting, because the machine is more heavily loaded in that condition. If the ripple amplitude is great enough, alternator whine will be imparted to all incoming signals by the LO.

Conducted noise can be minimized by connecting the radio power leads directly to the battery, as this is the point in the electrical system having the lowest impedance. If the regulator is adjustable, set the voltage no higher than is necessary to ensure complete battery charging. Radio equipment manufacturers combat voltage variations by internally regulating critical circuits wherever possible.

Both conducted and radiated noise can be suppressed by filtering the alternator leads. Coaxial capacitors (about 0.5  $\mu$ F) are suitable, but don't connect a capacitor to the field. The field lead can be shielded

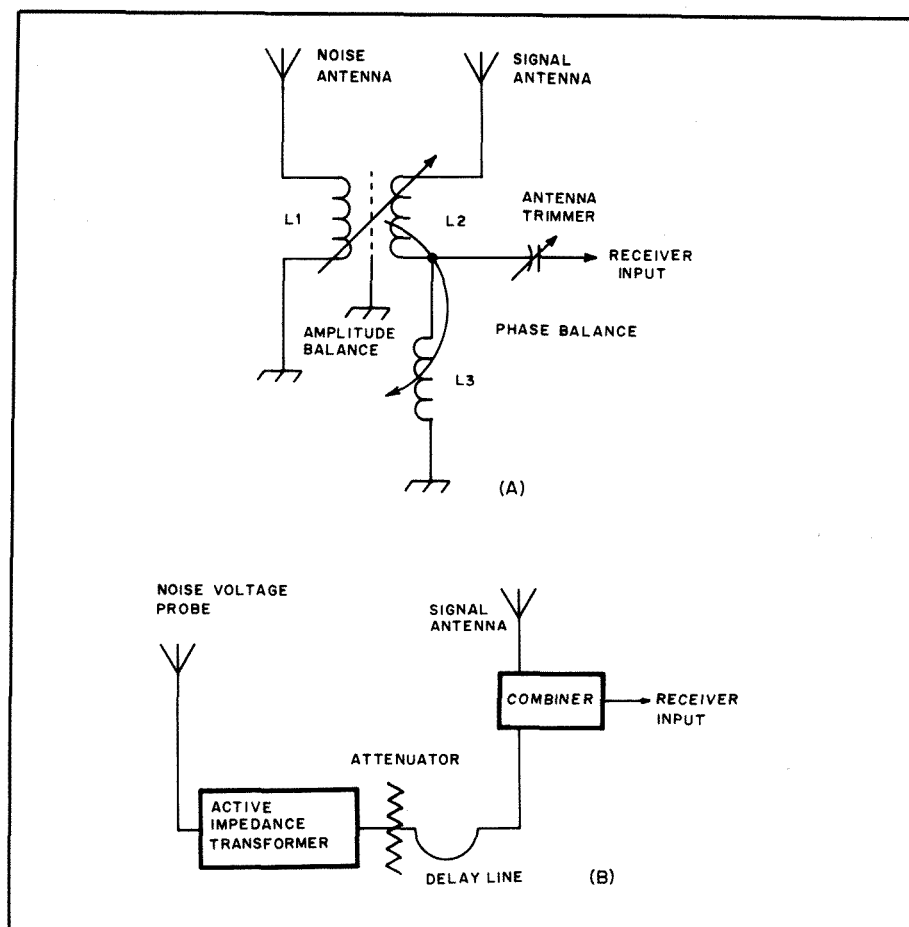

Fig. 78 — Automotive noise-cancelling systems. At A, the circuit used in the BC-342 HF receiver. At B, a suggested broad-band noise-cancelling scheme.

or loaded with ferrite beads if necessary. A parallel-tuned LC trap in this lead may be effective against radiated noise. Such a trap in the output lead must be made of no. 10 wire or larger, as some alternators conduct up to 100 amperes. The alternator slip rings should be kept clean to prevent excess arcing. An increase in "hash" noise may indicate that the brushes need to be replaced.

### Instrument Noise

Some automotive instruments are capable of creating noise. Among these gauges and senders are the heat- and fuel-level indicators. Ordinarily, the addition of a 0.5- $\mu$ F coaxial capacitor at the sender element will cure the problem.

Other noise-generating accessories are turn signals, window-opener motors, heating-fan motors and electric windshield-wiper motors. The installation of a 0.25- $\mu$ F capacitor will usually eliminate their interference.

### Corona-Discharge Noise

Some mobile antennas are prone to corona build-up and discharge. Whip antennas that come to a sharp point

will sometimes create this kind of noise. This is why most mobile whips have steel or plastic balls at their tips. But, regardless of the structure of the mobile antenna, corona buildup will frequently occur during or just before a severe electrical storm. The symptoms are a high-pitched "screaming" noise in the mobile receiver, which comes in cycles of one or two minutes' duration, then changes pitch and dies down as it discharges through the front end of the receiver. The condition will repeat itself as soon as the antenna system charges up again. There is no cure for this condition, but it is described here to show that it does not originate within the electrical system of the automobile.

### Electronic Noise Reduction

When all electrical noise generated within a vehicle has been eliminated, the mobile operator can be annoyed by RFI from passing vehicles. Some measures can be taken in the receiver to reduce or reject impulse noise. (Noise limiters and noise blankers are discussed in another chapter.) The placement of a noise blanker in the receiver is important. The blanking circuit must be placed ahead of the sharp selec-

tivity; otherwise, the IF filter will stretch the noise pulses, and they cannot be blanked without destroying a major portion of the received intelligence.

The Soviet "woodpecker" over-the-horizon radar has inspired some serious development work on noise blankers that don't degrade receiver dynamic range. Receivers for VHF FM service are generally designed for optimum noise figure at the expense of resistance to overload. Recent advances in RF amplifier design have proven that low noise figure and high dynamic range are not mutually exclusive. A high-performance noise blanker is useless if the front end of the receiver overloads on the noise pulses. A helical resonator at the receiver input affords some protection against noise overload because it restricts the total noise energy delivered to the front end.

Some FM receivers suffer from impulse noise because of inadequate AM rejection. The cure for this ailment is to ensure hard limiting in the IF stages and to use a detector that is inherently insensitive to amplitude variations.

Particularly troublesome vehicular impulse noise can sometimes be cancelled at the receiver input. The technique involves sampling the noise voltage from a separate "noise antenna" and adjusting its phase and amplitude to cancel the noise delivered by the "signal antenna." For this system to be effective, the signal antenna must be positioned to provide the best possible signal-to-noise ratio, and the noise antenna located close to the noise source and effectively shielded from the desired signal.

Fig. 78A shows the noise cancellation circuit used in some models of the BC-342, a WW II receiver. The Faraday shield between L1 and L2 ensures that the coupling is purely magnetic. The coupling between L2 and L3 is purely electrostatic. Adjusting the coil coupling causes the noise to null. The block diagram of Fig. 78B illustrates a more modern broadband approach to noise cancellation. A short wire near the ignition coil couples impulse energy into the active impedance transformer, which is simply an FET source follower stage. The amplitude and phase of the noise are controlled by the attenuator and delay line, respectively. The signal combiner can be a hybrid ferrite transformer at HF or a transmission line multi-coupler at VHF.

## PORTABLE STATIONS

Many amateurs experience the joys of portable operation once each year in the annual emergency exercise known as Field Day. Setting up an effective portable station requires organization, planning and some experience. For example, some knowledge of propagation is essential to picking the right band or bands for the intended communications link(s). Portable operation is difficult enough without dragging along excess equipment and antennas that will never be used.

Some problems encountered in portable operation that are not normally experienced in fixed-station operation include finding an appropriate power source and erecting an effective antenna. The equipment used should be as compact and lightweight as possible. A good portable setup is simple. Although you may bring gobs of gear to Field Day and set it up the day before, during a real emergency speed is of the essence. The less equipment to set up, the faster it will be operational.

## PORTABLE AC POWER SOURCES

There are two popular sources of ac power for use afield. The first is what is referred to as a dc-to-ac converter, or more commonly, an inverter.

The ac output voltage is a square wave. Therefore, some types of equipment cannot be operated satisfactorily from the inverter. Certain types of motors are among those items that require a sine-wave output. Fig. 79 shows a picture of one style of commercial inverter. Heat sinks are used to cool the switching transistors. It delivers 117 volts of ac at 175 watts continuous power rating. The primary voltage is 6 or 12 dc.

When sine-wave output is required from a portable ac power supply, gasoline-engine alternators are used. They are available with ratings of several kilowatts, or as little as 500 watts. One of the larger units is shown in Fig. 80 where WB9QPI has just completed a maintenance run for the W0OHU/0 Field Day group.

Alternators powered by internal-combustion engines have been used for years to supply 117/234-V ac independent of the commercial mains. Such combinations range from tiny units powered by two-cycle or four-cycle gasoline engines in the low-wattage class to giant multicylinder diesels capable of supplying megawatts of power. Perhaps the most practical power range for most purposes is in the neighborhood of 2 kW. Larger units tend to become too heavy for one person to lift and handle easily while smaller generators lack sufficient power output for many applications. A 2-kW alternator is quite heavy but is capable of supplying power for just about any large power tool. It is roughly the equivalent of having a single 15-A outlet in an ordinary electric service. Of course, it will handle moderate-power amateur equipment with ease.

## Maintenance Checklist

Although more complicated maintenance chores should be performed by qualified service personnel, many simple measures which will prolong the life of the alternator can be done at home or afield. Perhaps the best plan is to log the dates the unit was used and the operating time in hours. Also include dates of maintenance and type of service performed. Oil changes, when gasoline was purchased for emergency purposes, and

Fig. 79 — Photograph of a commercial dc-to-ac inverter that operates from 6 to 12 volts dc and delivers 117 volts ac (square wave) at 175 watts.

Fig. 80 — Large gasoline generators of the kilowatt and higher class are excellent for powering several amateur stations from a complex field site. Maintenance, as discussed in the text, is a vital matter to ensure reliable operation. Here, WB9QPI has just finished a maintenance check of the group's Field Day power plant.

Fig. 81 — The numbers indicate the primary maintenance points of a large power generator (see text for details).

Fig. 82 — A simple accessory that provides overload protection for generators that do not have such provisions built in.

similar data would fall under this category.

Important points common to all types of generators are indicated for a typical one in Fig. 81. (Consult the manufacturer's manual for additional instructions that might apply to a particular model.) The following checklist relates to the numbers on the drawing.

1) Use the proper grade of fuel. Check the owner's manual to determine whether oil must be mixed with the gasoline. While two-cycle models require an oil-gas mixture, most generators have a four-cycle engine that burns ordinary gasoline with no extra additives. Gasoline for emergency purposes should be stored only in small amounts and rotated on a regular basis. Older stock can be burned in a car (that uses the same grade of gas as the generator) since storing gasoline for any length of time is inadvisable. The more volatile components evaporate, leaving excess amounts of a varnish-like substance that will clog carburetor passages. Also, be sure gasoline containers are of an approved type with a clean interior, free of rust or other foreign matter. Similar considerations apply to the gas tank on the engine itself.

The majority of difficulties with small engines are related to fuel problems in some way. Dirty fuel or water in the gasoline is one source, with carburetor trouble because of the use of old gas being another common cause. Except for minor adjustments recommended in the instruction manual, it is seldom necessary to touch the carburetor controls. Avoid the temptation to make such adjustments in the case of faulty operation. Follow the recommendations in this guide so that more complicated maintenance procedures (such as carburetor overhaul) are not required.

2) Another important factor often

Fig. 83 — A simple portable antenna mast may be built from telescoping tubing sections. The mast is assembled and bolted together on the ground, and the antennas attached. The mast is then pushed into the air and guyed in place. If slip-ring guy collars are used, the entire mast may be rotated by hand from ground level. A dipole may be used as part of the guy system.

neglected in maintenance of alternator engines is oil. While lubrication is one job oil has to perform, there are other considerations as well. The engine oil in the crankcase also collects a large amount of solid combustion products, bits of metal worn away by the moving parts, and any dust or other foreign matter that enters the carburetor intake. For instance, it is especially important to observe the manufacturer's recommendations concerning the length of time the engine may be operated before an oil change is required during the break-in period. If you ever have the opportunity to examine the oil from a new engine, you will note a metallic sheen to it. This is from the excessive amount of metal that is worn away. After the break-in period, much less metal is abraded and the oil doesn't have to be replaced as often.

The oil level should be checked frequently during engine operation. Each time fuel has to be added the oil should be checked also. When storing an alternator, it is also wise to drain the oil and replace it with fresh stock. This is because one of the combustion products is sulfur, which forms sulfuric acid with water dispersed in the oil. The acid then attacks the special metal in the bearing surfaces causing pitting and the need for premature replacement.

Also note the grade and weight of oil

recommended by the manufacturer. Unlike their larger counterparts in automobiles, most small engines do not have oil filters, which is another reason required changes are more frequent. Some manufacturers recommend a high-detergent oil that comes in various service grades such as MS and SD. Examine the top or side of the cans in which the oil is sold and see if the letters correspond to those recommended by the engine manufacturer.

3) The carburetor mixes gasoline with air, and the mixture is then burned in the engine. Before entering the carburetor, the air must be filtered so it is free of dust and other foreign matter that might otherwise be drawn into cylinder(s). Particles that do get by the air filter are picked up by the oil. (Oil should be changed more often if the alternator is operated in a dusty location.) Also, it is important to clean the air filter frequently. It contains a foam-like substance that can be cleaned in kerosene and then soaked in fresh motor oil. Squeeze excess oil from the filter before replacing. Also, consult the instruction manual for further recommendations.

4) Once the gas/air mixture enters the cylinder, it is compressed by the piston into a very small volume and ignited by the spark plug. During the rapid burning that then occurs, the expansion caused by the resulting heat forces the piston down and

Fig. 84 — An aluminum extension ladder makes a simple but sturdy portable antenna support. Attach the antenna and feed lines to the top ladder section while it is nested and laying on the ground. Push the ladder vertical, attach the bottom guys and extend the ladder. Attach the top guys. Do not attempt to climb this type of antenna support.

delivers the mechanical power to the alternator.

As might be expected, proper operation of the ignition system is an important factor in engine performance. Power for the spark is supplied by a device called a magneto that is normally installed on the front of the engine. The magneto seldom requires servicing and such work should only be done by those qualified to do so. (This is one reason the magneto is often located under a flywheel that is difficult to remove by the inexperienced.)

Faulty spark plugs are the usual cause of ignition problems. Special equipment is required to test a spark plug properly, but an easier solution is to have a new one handy. In fact, keep two spare plugs on hand. Spark plug life can be notoriously short on occasion. However, repeated plug

failure is also abnormal; other causes such as a poor gas/air mixture might be the culprit.

Replace the spark plug with a type similar to the one that came with the alternator or a substitute recommended by the manufacturer. Some models have resistor-type plugs, which are desirable for ignition-noise suppression. Resistor plugs are usually indicated by an R prefix. For instance the resistor version of a Champion CJ-8 would be an RC-J8.

5) Little exhaust system maintenance is required. In some forested areas, a spark-arrester type of muffler is required, so be sure your unit is so equipped before operating in such a location. "Quiet hours" may also be imposed in some places during the nighttime hours if generator exhaust noise is too loud.

(B)

Fig. 85 — The portable tower mounting system described by WA7LYI in the text. At A, a truck is "parked" on the homemade base plate to weigh it down. At B, the antennas, mast and rotator are mounted before the tower is pushed up. Do not attempt to climb a temporary tower installation.

Two very important safety precautions should be observed with regard to the exhaust system. Never operate an alternator in closed surroundings such as a building. Dangerous gases are emitted from the exhaust. Second, never refuel an engine while it is running or if the exhaust system is still very hot. Unfortunately, this last precaution is disregarded by many, which is extremely foolish. (Experienced service station operators will refuse to refuel an automobile with the motor running, a practice that is often prohibited by law.) Don't become an unnecessary statistic.

6) Most alternators are air-cooled as opposed to the water-cooled radiator system of the automobile. A fan on the front of the engine forces air over the cylinder. Avoid operating the alternator in areas where obstruction to this flow might result (such as in tall grass). Alternators should be operated such that a sufficient amount of air circulation is present for cooling, carburetion and exhaust.

### Storage

Proper maintenance of an alternator when it is not being used is just as important as during the time it is in operation. The usual procedure is to run the engine dry of gasoline, drain the crankcase and fill it with fresh oil, and remove the spark plug. Then pour a few tablespoons of oil into the cylinder and turn the engine over a few times with the starter and replace the plug. But never crank the engine with the plug removed and the ignition or start switch in the on or run position. The resulting no-

(C)

Fig. 86 — The portable mast and tripod described by WA7LYI in the text. At A, the tripod is clamped to stakes driven into the ground. The rotator is attached to a homemade pipe mount. At B, rocks piled on the rotator mount keep the rotator from twisting and add weight to stabilize the mast. At C, a 10-foot mast is inserted into the tripod/rotator base assembly. Four 432-MHz quagis are mounted at the top.

load high voltage might damage the magneto. It is also a good idea to ground the spark-plug wire to the engine frame with a clip lead in case the switch is accidentally activated.

Moisture is the greatest enemy of an iron product — such as a generator — in storage. The coating of oil helps retard rust formation that might actually weld the two surfaces when the engine is restarted, resulting in premature wear. Consequently, it is important to store the alternator in an area of low humidity.

Although the maintenance procedures outlined may seem like a chore, the long-term benefits include low repair costs and like-new performance. Engines for alternator combinations must be able to handle a variety of loads while maintaining a constant speed in order to keep the output frequency constant. A mechanical governor performs this latter function by metering the fuel supplied to the engine under different load conditions. However, the system cannot function properly with an engine in poor mechanical condition because of lack of proper maintenance.

### Grounds

Newer generators are supplied with a three-wire outlet, and the ground connection should go to the plug, as shown in Fig. 82. On older types, the ground would have to be connected separately to the generator frame and then to the common terminal in the junction box. A pipe or rod can then be driven into the ground and a wire connection made to either a clamp supplied with the rod or by means of a C-clamp for larger sizes of pipe. From an ignition-noise-

suppression standpoint, the ground is desirable along with safety considerations when power tools are being used.

The ground connection goes to the green wire in commercially made three-wire conduit. Conduit purchased from an electrical store comes with a color-coded insulation and the colored wires should be connected as shown in Fig. 82. Consult the owner's manual for the generator for further details on power hookup that might apply to your particular model.

### PORTABLE ANTENNA CONSIDERATIONS

An effective antenna system is essential to all types of operation. Effective portable antennas, however, are more difficult to devise than their fixed-station counterparts. A portable antenna must be light, compact and easy to assemble. It is also important to remember that the portable antenna may be erected at a variety of sites, not all of which will offer ready-made supports. Strive for the best antenna system possible because operations in the field are often restricted to low power by power supply and equipment considerations. Some antennas suitable for portable operation are described in Chapter 33.

### Antenna Supports

While some amateurs have access to a truck or trailer with a portable tower, most are limited to what nature supplies, along with simple push-up masts. If possible, select a portable site as high and clear as possible. Elevation is especially important if your operation involves VHF. Trees, buildings, flagpoles, telephone poles and

the like can be pressed into service to support wire antennas. Usually, drooping dipoles are chosen over horizontal dipoles because they require only one support.

A portable mast up to 30 feet high can be constructed from telescoping tubing sections, as shown in Fig. 83. A mast of this type can be used as a wire-antenna support, or it could support a small triband beam or VHF array. If the guy collars allow the mast to slip, the entire mast may be rotated by hand. Some of the guy wires may be used for wire antennas. The limiting factor in terms of height with a mast of this type is the number of people required to push it into place.

An aluminum extension ladder makes an effective antenna support, as shown in Fig. 84. In this installation, a mast, rotator and beam are attached to the top of the second ladder section with the ladder near the ground. The ladder is then pushed vertical and the lower set of guy wires attached to the guy anchors. When the first set of guy wires is secured, the ladder may be extended and the top guy wires attached to the anchors. Do not attempt to climb a temporarily guyed ladder.

Figs. 85 and 86 illustrate two methods for mounting portable antennas described by Terry Wilkinson, WA7LYI. Although the antennas shown are used for VHF work, the same principles can be applied to small HF beams as well.

In Fig. 85A, a 3-foot section of Rohn 25 tower is welded to a pair of large hinges, which in turn are welded to a steel plate measuring approximately 18 × 30 inches. One of the rear wheels of a pickup truck is "parked" on the plate, ensuring that it

will not move. In Fig. 85B, a quad array of antennas for 144 and 220 MHz are mounted on a Rohn 25 top section, complete with rotator and feed lines. The tower is then pushed up into place using the hinges, and guy ropes anchored to stakes driven into the ground complete the installation. This method of portable tower installation offers an exceptionally easy-to-erect, yet sturdy, antenna support. Towers installed in this manner may be 30 or 40 feet high; the limiting factor is the number of "pushers" and "rope pullers" needed to get it into the air. A portable station located in the bed of the pickup truck completes the installation.

The second method of mounting portable beams described by WA7LYI is shown in Fig. 86. This support is intended for use with small or medium sized VHF and UHF arrays. The tripod is available from any dealer selling television antennas; tripods of this type are usually mounted on the roof of a house. Open the

tripod to its full size and drive a pipe into the ground at each leg. Use a hose clamp or small U-bolt to anchor each leg to its pipe.

The rotator mount is made from a 6-inch-long section of 1½-inch-diameter pipe welded to the center of an "X" made from two 2-foot-long pieces of concrete reinforcing rod (rebar). The rotator clamps onto the pipe, and the whole assembly is placed in the center of the tripod. Large rocks placed on the rebar hold the rotator in place, and the antennas are mounted on a 10 or 15-foot mast section. This system is easy to make and set up.

#### **Tips for Portable Antennas**

Any of the antennas described in Chapter 33 or available from commercial manufacturers may be used for portable operation. Generally, though, big or heavy antennas should be passed over in favor of smaller arrays. The couple of decibels of gain a 5-element, 20-meter beam may have

over a 3-element version is insignificant compared to the mechanical considerations. Stick with arrays of reasonable size that are easily assembled.

Wire antennas should be cut to size and tuned prior to their use in the field. Be careful when coiling these antennas for transport, or you may end up with a tangled mess when you need an antenna in a hurry. The coaxial cable should be attached to the center insulator with a connector for speed in assembly. Use RG-58 for the low bands and RG-8X for higher-band antennas. Although these cables exhibit higher loss than standard RG-8, they are far more compact and weigh much less for a given length.

Beam antennas should be assembled and tested before taking them afield. Break the beam into as few pieces as necessary for transportation and mark each joint for speed in reassembly. Hex nuts can be replaced with wing nuts to reduce the number of tools necessary.

## Chapter 38

# Operating a Station

This Handbook serves primarily the technical phases of Amateur Radio — and indeed radio/electronics in general. As far as hamming is concerned, only about half the game deals with how you handle the soldering iron. The other half is concerned with what you do with your radio equipment once you get it operating. This is the subject of this chapter, and the real fun of Amateur Radio!

The *ARRL Operating Manual* is the definitive source of information on all phases of on-the-air activity for radio amateurs and goes into more detail than we can here. You can purchase a copy from ARRL Hq. or from your local dealer. Newcomer and veteran alike will profit from in-depth treatment of everything from DXing to digital communications. This publication is available at your local dealer or direct from ARRL Hq.

### Operating Standards

Through the years, Amateur Radio has developed a number of operating standards and procedures. Some of these are borrowed from other services, such as commercial or military. Some have been coined by amateurs for our particular use, as a part of “ham jargon.” Still others have been innovated by the League to fulfill a need. All of them together make up a “standard operating procedure” for amateurs that differs, at least in part, from the procedures used in any other radio service. ARRL recommends standard procedures that are based on our particular needs. If we all use different procedures, we will have difficulty, at times, in communicating with each other. Let’s all use the same standard and be a single organized, operating service.

### Establishing Contact

If you are looking for a contact with anyone, then you may want to call “CQ.” Before your signal uses valuable spectrum space, however, listen to see if the frequency appears to be in use. Follow that

Amateur Radio is enriched by the influx of enthusiastic young operators such as Mike, KA3HID.

up with, “Is the frequency in use?” on voice, or QRL? on CW. You don’t need a long CQ — just a  $3 \times 3$ . If still no answer, it means one of two things: Either no one heard you or no one listening wants to contact you. Try it again, another  $3 \times 3$ . If still no answer, that’s enough. Move to another (clear) frequency before you try it again. A CQ call on CW might go like this: CQ CQ CQ DE AB1U AB1U AB1U K. On voice, “CQ CQ, this is AB1U, Alfa Bravo One Uniform, go ahead.”

If you call CQ, it means you are willing to talk to anyone. If you want to be fussy, don’t call CQ: Find someone you would like to talk to and call that person. In this case, you can observe the same principle; zero beat his frequency and give him a short call, such as: K1MM K1MM K1MM DE VE3GT VE3GT AR, or even shorter. On voice, “K1MM K1MM from VE3GT Victor Echo Three Golf Tango, over.”

Notice the “ending signals.” These aren’t just happenstance; each one of them means something. On CW for example, k at the end of a transmission means “anyone go ahead,” while AR means “I

have just called another station and want only him to reply. On voice, “go” or “go ahead” refers to anybody listening, while “over” refers to a specific station. And so on. There is a complete list of ending pro-signs and pro-words. Use them properly, even if others you hear do not.

Now about the QSO itself. You are introducing yourself to a brand-new acquaintance. Don’t bore him. The usual procedure is to give your name and location. After that, tell him the things about yourself that you would like to know about him, but make your transmissions short. Most voice operators use VOX or push to talk, which makes it possible to talk back and forth rapidly, much like a telephone conversation. Identification of your station during each transmission is unnecessary, but be sure to sign your call at least once every 10 minutes during the course of the QSO and at the conclusion of the QSO.

### The ARRL QSL Bureaus

Only one thing is left to do before you can consider the contact complete — confirm it with a QSL card. The QSL is con-

Table 1

## Some Facts About Time Conversion

This chart has been arranged to show UTC and the time zones used by most amateurs in North America. Universal Coordinated Time is the standard reference time used throughout the world. ARRL recommends that all amateur logging be done in UTC.

All times shown are in 24-hour time for convenience. To convert to 12-hour time: For times between 0000 and 0059, change the first two ciphers to 12, insert a colon and add A.M.; for times between 1200 and 1259, insert a colon and add P.M.; for times between 1300 and 2400, subtract 12, insert a colon and add P.M.

Time zone letters may be used to identify the kind of time being used. For example, UTC is designated by the letter Z, EDT/AST by the letter Q, CDT/EST by R, MDT/CST by S, PDT/MST by T, PST by U; thus, 1200R would indicate noon in the CDT/EST zone, which would convert to 1700 UTC or 1700Z.

In converting from one time to another, be sure the day or date corresponds to the new time. That is, 2100R (EST) on January 1 would be 0200Z (UTC) on January 2; similarly, 0400Z on January 2 would be 2000U (PST) on January 1.

A good method is to use UTC (Z) for all amateur logging, schedule-making, QSLing and other amateur work. Otherwise, confusion with all the different time zones is inevitable. Leave your clock on UTC. Most of Alaska and Hawaii use W time (UTC + 10 hrs.)

Time changes one hour with each change of 15° in longitude. The five time zones in the U.S. proper and Canada roughly follow these lines.

0000\* and 2400 are interchangeable; 2400 is associated with the date of the day ending, 0000 with the day just starting.

UTC	AST/EDT	EST/CDT	CST/MDT	MST/PDT	PST
0000*	2000	1900	1800	1700	1600

2400	2000	1900	1800	1700	1600

sidered the final courtesy of a contact and is an Amateur Radio tradition. Most amateurs have printed cards, some personalized (at greater cost), some using standard setups provided by printers for the purpose. Whatever form you adopt, be sure your QSL card shows very clearly the correct call of the station contacted, the date (including year) and UTC time, the band on which contact was made, and the mode. Most awards based on QSL cards require at least these essentials, along with, of course, your street address, city, state

or province, and country. Some awards require your county as well. Other interesting data might include some details of your equipment, antennas, former calls held, class of license, signal report and any friendly comments.

If everybody waited to receive a card before sending one, there would be no QSLing. Admittedly, printing and postage are expensive. If you are very active on the air, QSLing every contact may seem like a needless expense. If you want a QSL from your contact, be sure to send your card; and as a matter of common courtesy, send a card to everyone who sends you one.

## Receiving DX QSLs

Within the U.S. and Canada, the ARRL DX QSL Bureau System is made up of 22 call area bureaus. Most of the cards from DX bureaus go directly to the individual bureaus.

At the individual bureaus, the incoming cards are sorted by the first letter of the suffix. This sorting divides the work load into portions that can be handled by a single individual.

To claim your cards, send a 5 × 7½ inch, self-addressed stamped envelope to the bureau serving your district. (Addresses for the U.S. and Canadian bureaus are shown twice a year in *QST* in the "QSL Corner" column, or send an s.a.s.e. to ARRL Hq. for QSL bureau information.) These envelopes should have your call sign printed neatly in the upper-left corner of the envelope to assist the sorter of your cards. Some bureaus will sell envelopes or postage credits as well as handling s.a.s.e.'s. The bureau will provide the proper size envelope and affix appropriate postage upon prepayment of a certain fee. The exact arrangement of your area bureau can be obtained by sending the bureau an

s.a.s.e. with your inquiry.

Since many of the overseas stations use the bureau system, this area bureau can be very important to someone who works DX. It is a complex volunteer arrangement requiring good cooperation on the part of the DXers to function properly.

## Sending Your DX QSLs

Each month, every member of the ARRL (except family and sightless members) is mailed a copy of *QST*. The address label on the wrapper of *QST* is the member's "ticket" for use of the Overseas QSL Service. Twelve times per year, an ARRL member may send any number of QSL cards for amateurs overseas. With each mailing the member must include the address label from the current copy of *QST* and \$1 (check or money order) for each pound or part of a pound of cards; approximately 155 cards weigh one pound. QSLs must be presorted by prefix. Include only the cards, address label and money in the package. Wrap the package securely and address it to ARRL-Membership Overseas QSL Service, 225 Main St., Newington, CT 06111.

Family members of the ARRL may send cards in the same package but must include \$1 per pound for each member sending cards and indicate that the *QST* address label includes a "family membership."

Sightless members, who do not receive *QST*, need only include \$1 per pound with a note indicating that the cards are from a sightless member. Associate (unlicensed) members may use the Overseas QSL Service to send SWL reports to overseas amateur stations. No cards will be sent to individual QSL managers.

Additional information is available from ARRL Hq. Send an s.a.s.e. and request the QSL Bureau reprint.

Table 2

## ARRL Communications Procedures

Voice	Code	Situation
Go ahead	K	Used after calling CQ, or at the end of a transmission, to indicate any station is invited to transmit.
Over	AR	Used after a call to a specific station before the contact has been established.
	KN	Used at the end of any transmission when only the specific station contacted is invited to answer.
Stand by or wait	AS	A temporary interruption of the contact.
Roger	R	Indicates a transmission has been received correctly and in full.
Clear	SK	End of contact. SK is sent <i>before</i> the final identification.
Leaving the air or closing station	CL	Indicates that a station is going off the air, and will not listen for or answer any further calls. CL is sent after the final identification.

See inside front cover. Output in Watts. UTC recommended. RST. See back inside cover. This column may also be used for contest exchange info. received.

The ARRL Log is adaptable for all types of operating — ragchewing, contesting, DXing. References are to pages in the ARRL Log.

### Your Station Record — Logging

Although the FCC does not require you to keep a log, an accurate, complete and neat log book can be a matter of personal pride. It can also be a strong form of protection for you against possible claims by others of intentional interference, or against troubles caused by unauthorized use of your call by others.

A log should be convenient to use — a bound one is best, so pages will not be lost. Your log becomes a written diary of your amateur operation and should include everything that will be of interest to you in years to come. Most amateurs retain their logs indefinitely as a historical record.

### The Voice Modes

The use of proper procedure to get best results is very important. Voice operators say what they want to have understood, while CW operators have to spell it out or abbreviate. Since on phone the speed of transmission is generally between 150 and 200 words per minute, the matter of readability and understandability is critical to good communications. The good voice operator uses operating habits that are beyond reproach.

### Phone Operating Practices

Listen with care. It is very natural to answer the loudest station that calls, but with a little digging, if need be, answer the best signal instead. Not all amateurs can run a kilowatt, but there is no reason every amateur cannot have a signal of the highest quality. Do not reward the operator who cranks up the transmitter gain and splatters by answering him if another station is calling.

Use VOX or push-to-talk. If you use VOX, don't defeat its purpose by saying "aah" to keep the relay closed. If you use push-to-talk, let go of the mic button every

so often to make sure you are not "doubling" with the other station. Don't be a monologist.

Listen before transmitting. Make sure the frequency isn't being used before you come barging onto it. If you don't hear any station on the frequency, make this announcement: "Is the frequency in use? WB5LUA." If it is still clear, you are ready to make your call.

Interpose your call frequently, in distinct, measured tones. Use approved phonetics if your call sign is hard to understand or if conditions are poor. Remember you can be cited for improper identification if it cannot be understood.

Keep microphone (mic) gain constant. Don't "ride" the mic gain. Try to speak in an even amplitude the same distance from the microphone, keeping the gain down to eliminate room noise. Follow the manufacturer's instructions for use of the microphone; some require close-talking, while some need to be turned at an angle to the speaker's mouth.

The speed of radiotelephone transmission (with perfect accuracy) depends almost entirely on the skill of the two operators concerned. Use a rate of speech that allows perfect understanding as well as permitting the receiving operator to record the information.

### Voice Operating Hints

- 1) Listen before calling.
- 2) Make short calls with breaks to listen. Avoid long CQs; do not answer overlong CQs.
- 3) Use push-to-talk or voice control (VOX). Give data concisely in first transmissions.
- 4) Make reports honest. Use definitions of strength and readability for reference. Make your reports informative and useful.
- 5) Limit transmission length. Two

minutes or less will convey much information. When three or more stations converse in roundtables, brevity is essential.

6) Display sportsmanship and courtesy. Bands are congested — make transmissions meaningful — give others a break.

7) Check transmitter adjustment — avoid splatter. Check speech-processor adjustment. Do not transmit when moving VFO frequency. Complete testing before busy hours — use a dummy load!

### Repeater Operating

A repeater is a device that receives a signal on one frequency and simultaneously transmits (repeats) it on another frequency. Often located atop a tall building or high mountain, VHF and UHF repeaters greatly extend the operating coverage of amateurs using mobile and hand-held transceivers.

To use a repeater you must have a transceiver with the capability of transmitting on the repeater's input frequency (the frequency that the repeater listens on) and receiving on the repeater's output frequency (the frequency the repeater transmits on). This capability can be acquired by dialing the correct frequency and selecting the proper offset (frequency difference between input and output).

When you have the frequency capability, all you need do is key the microphone button and you will turn on (access) the repeater. Some repeaters have limited access, requiring the transmission of a subaudible tone, a series of tones or bursts in order to gain access. Most repeaters briefly transmit a carrier after a user has stopped transmitting to inform the user that he is actually accessing a repeater.

After acquiring the ability to access a repeater, you should become acquainted with the operating practices that are inherent to this unique mode of Amateur Radio:

**Table 3****International Telecommunication Union Phonetics**

A — Alfa	J — Juliett	S — Sierra
B — Bravo	K — Kilo	T — Tango
C — Charlie	L — Lima	U — Uniform
D — Delta	M — Mike	V — Victor
E — Echo	N — November	W — Whiskey
F — Foxtrot	O — Oscar	X — X-Ray
G — Golf	P — Papa	Y — Yankee
H — Hotel	Q — Quebec	Z — Zulu
I — India	R — Romeo	

1) Monitor the repeater to become familiar with any notable features in its operation.

2) To initiate a contact simply indicate that you are on frequency. Various geographical areas have different practices on making yourself heard, but, generally, "This is W1XX monitoring" will suffice. One practice that is usually looked upon with disfavor throughout the U.S. and Canada is calling CQ on a repeater.

3) Identify legally. You must transmit your call sign at the end of each contact and every 10 minutes during each contact. It is illegal to "kerchunk" a repeater (transmit an unmodulated carrier) without identifying, as this constitutes an unidentified transmission.

4) Pause between transmissions. This allows other hams to use the repeater (someone may have an emergency). On most repeaters a pause is necessary to reset the timer.

5) Keep transmissions short and thoughtful. Your monologue may prevent someone with an emergency from using the repeater. If your monologue is long enough, you may time-out the repeater. Your transmissions are being heard by many listeners, including nonhams with public service band monitors and scanners; don't give a bad impression of Amateur Radio.

6) Use simplex whenever possible. If you can complete your QSO or contact on a direct frequency, there is no need to tie up the repeater and prevent others from using it.

7) Use the minimum amount of power necessary to maintain communications. This FCC regulation minimizes the possibility of accessing distant repeaters on the same frequency.

8) Don't break into a contact unless you have something to add. Interrupting is no more polite on the air than it is in person.

9) Many repeaters are equipped with autopatch facilities which, when properly accessed, connect the repeater to the telephone system to provide a public service. The FCC forbids using an autopatch for anything that could be construed as business communications. An autopatch should not be used to avoid a toll call. Do not use an autopatch where regular telephone service is available. Abuses of autopatch privileges may lead to their loss.

10) All repeaters are assembled and

This W1AW 120-foot tower holds phased 4-element, 20-meter Yagis at 60 and 120 feet and a 2-element, 40-meter Yagi at 90 feet.

maintained at considerable expense and inconvenience. Usually an individual or a group is responsible, and those who are regular users of a repeater should support the efforts of keeping the repeater on the air.

The ARRL *Repeater Directory*, listing approximately 10,000 amateur repeaters, is published annually by ARRL.

### CW Operating

If you spend an entire Amateur Radio career on phone once you have mastered enough CW to pass the necessary tests, you are missing out on at least 50 percent of the fun of hamming. Mastering the art of CW communication is 10 times easier than learning to talk, and you did that when you were two years old. All it takes is some basic learning principles, then practice. This is not drudgery as you might think, because you can combine learning with listening to actual signals on the band, and even with operating, since the Novice class license requires only 5 WPM.

But listening is the best way to go, in the

beginning. You don't need a license for that. Once you have learned the basic sounds of code, you will soon start recognizing common words — the, and, CQ, DE (from), etc. Copying calls is an excellent means of getting prelicense practice. You can even get good sending practice by pretending to call the CQing station on your code practice oscillator. Sending practice is important. Start with a simple "straight" key; later you can switch to an electronic keyer.

There are many pitfalls to developing into a finished CW operator, not the least of which is the acquisition of bad habits. Many of these come from mimicking your peers or elders, some of whom are themselves the victims of bad CW habits. Don't let undesirable operating habits rub off on you.

Probably the worst of these is carelessness about spacing. Your early CW training should have taught you that spacing length is just as important as dit and dah length. One way to improve your spacing is to practice sending "in step" with W1AW using a code practice oscillator (but not on the air!). If you can send in step with W1AW, your sending is perfect. The source of each W1AW code practice test is sent several times during the transmission to enable you to check your copy.

On phone it is unnecessary and therefore improper to use jargon and abbreviations, but on CW abbreviations are a necessity. Without them, it takes a long time to say what you want to say, especially at beginner speeds. Most of the abbreviations hams use have developed within the fraternity; some of them are borrowed from or are carryovers from old-time telegraphy abbreviations. Which is which doesn't matter; it is all ham radio to us. Learn to use ham CW abbreviations liberally and you will get much more said in much less time. When you reach a high-proficiency level, you will find that CW is almost as fast as talking, thus all but eliminating one of its principal disadvantages while still retaining its many advantages.

Despite the fact that learning CW is easier than learning to talk, nearly everybody can talk but few people can communicate by CW. Thus, there is considerable pride of accomplishment in CW operating. Regardless of your level of proficiency, chances are that you still have something to learn about CW operating, additional proficiency goals you can achieve. ARRL offers a series of awards in this field, starting at 10 WPM and progressing all the way through 40 WPM, in 5-WPM increments. You will find more details elsewhere in this chapter.

Copying CW and comprehending it are not the same thing. The word "copy" implies something written, so "if you don't put it down, that ain't copying." On the other hand, for conversational CW purposes, copying really isn't necessary and can be quite cumbersome. Most beginners

on CW learn by copying everything down, and some find that this habit is hard to break as they achieve higher levels of proficiency. However, it does involve a "translation" process that can and should be eliminated for conversational purposes. Sooner or later, in order to realize the full value of CW communication, you must learn just to listen to it, as you do the spoken word, rather than to "copy" it. It should not be necessary to translate the CW into written copy and then translate the written copy into intelligence by reading it. Eventually, the sound of code should directly trigger your consciousness just as the spoken word does, and then the "copy" and understanding functions are reversed; that is, you understand it first, then you copy it.

CW is not just something that has been imposed on us to make passing the amateur test a little more difficult. It is an entirely different method of communication, and a long way from obsolete. Learn it well and your enjoyment of Amateur Radio will be enriched.

### Amateur Television Operating

Amateur television (ATV) has much in common with commercial image-transmission systems. Amateur fast-scan television (FSTV) has borrowed equipment and techniques from broadcast television. Commercial freeze-frame systems are to some extent a spin-off of amateur slow-scan television (SSTV) developments. There are some differences that make ATV distinctive. ATV is a two-way operation,

which gives it the potential of being highly interactive. Owing to transmitter power limitations and the insatiable desire of amateurs to work DX, ATV operators are usually willing to sacrifice quality and signal-to-noise ratio for range.

FSTV and SSTV are primarily image-transmission media, often with an audio channel. Many amateurs who start out in ATV point a camera at themselves, their shack, their household pet (wearing ear-phones, of course) and then run out of ideas. After everyone on the repeater has had a few nights of this, there is inevitably a discussion of how to get some "new blood" in the group. ATV is a visual medium, and the artistic aspects of operating deserve some attention.

What can you do to make ATV useful and interesting? Well, the FCC rules say you can't transmit music or broadcast to the general public. That leaves a tremendous number of possibilities for ATV. It takes some planning, a reasonable amount of equipment, and some follow-through to make full use of the medium. Much can be learned from still photography and home video, which is largely supplanting home movies. These are tools that can be used to prepare material for ATV transmission. Character generators and special effects can spice up an ATV transmission. FSTV lends itself to transmission of prerecorded video tapes on subjects of interest to radio amateurs, such as technical talks and training courses. Portable and mobile operating adds to the fascination of FSTV. Emergency communications, two-way TV

third-party conversations possibly involving sign language for the deaf, and assisting in coordination of special events, are but a few FSTV applications that have been tried. Some spectacular color still photography is being transmitted via SSTV these days. The creative side of ATV is only beginning.

For either FSTV or SSTV, it is useful to have a good selection of test patterns for measuring the quality of both equipment and the communications channel. Several test charts are available from the Electronic Industries Association (EIA), the International Radio Consultative Committee (CCIR), and the International Telegraph and Telephone Consultative Committee (CCITT) for FSTV and facsimile.<sup>1</sup> In addition, you may want to make your own, either mechanically or electronically. Mechanical test charts can be made on poster board by combining line drawings, hand or press-on lettering, press-on shading and colored paper with photographs. Test charts can be generated electrically with a personal computer that can produce letters, and black-and-white graphics. Computers with a color capability can be used to make color bars, a gray scale and other useful patterns.

### Fast-Scan Television Operating

Amateur fast-scan television (FSTV) is

<sup>1</sup>Contact EIA at 2001 Eye St., N.W., Washington, DC 20006. CCIR and CCITT materials are available from the U.N. Bookstore, United Nations Building, New York, NY 10017.

**Table 4**  
**Q Signals**

These Q signals are the ones whose meanings most often need to be expressed with brevity and clearness in CW amateur work. (Q abbreviations take the form of questions only when followed by a question mark.)

QRG	Will you tell me my exact frequency (or that of ___)? Your exact frequency (or that of ___) is ___ kHz.	QRV	Are you ready? I am ready.	QSV	Shall I send a series of Vs on this frequency (or ___ kHz)? Send a series of Vs on this frequency (or on ___ kHz).
QRH	Does my frequency vary? Your frequency varies.	QRW	Shall I inform ___ that you are calling him on ___ kHz. Please inform ___ that I am calling him on ___ kHz.	QSW	Will you send on this frequency (or on ___ kHz)? I am going to send on this frequency (or on ___ kHz).
QRI	How is the tone of my transmission? The tone of your transmission is ___ (1. Good; 2. Variable; 3. Bad).	QRX	When will you call me again? I will call you again at ___ hours (on ___ kHz).	QSX	Will you listen to ___ on ___ kHz? I am listening to ___ on ___ kHz.
QRK	What is the intelligibility of my signals (or those of ___)? The intelligibility of your signals (or those of ___) is ___ (1. Bad; 2. Poor; 3. Fair; 4. Good; 5. Excellent.)	QSA	What is the strength of my signals (or those of ___)? The strength of your signals is ___ (1. Scarcely perceptible; 2. Weak; 3. Fairly good; 4. Good; 5. Very good).	QSY	Shall I change to transmission on another frequency? Change to transmission on another frequency (or on ___ kHz).
QRL	Are you busy? I am busy (or I am busy with ___). Please do not interfere.	QSB	Are my signals fading? Your signals are fading.	QSZ	Shall I send each word or group more than once? Send each word or group two (or ___ times).
QRM	Is my transmission being interfered with? Your transmission is being interfered with ___ (1. Nil; 2. Slightly; 3. Moderately; 4. Severely; 5. Extremely.)	QSD	Are my signals defective? Your signals are defective.	QTA	Shall I cancel message number ___? Cancel message number ___.
QRN	Are you troubled by static? I am troubled by static ___.	QSG	Shall I send ___ messages at a time? Send ___ messages at a time.	QTB	Do you agree with my counting of words? I do not agree with your counting of words; I will repeat the first letter or digit of each word or group.
QRO	Shall I increase power? Increase power.	QSK	Can you hear me between your signals and if so can I break in on your transmission? I can hear you between my signals; break in on my transmission.	QTC	How many messages have you to send? I have ___ messages for you (or for ___).
QRP	Shall I decrease power? Decrease power.	QSL	Can you acknowledge receipt? I am acknowledging receipt.	QTH	What is your location? My location is ___.
QRQ	Shall I send faster? Send faster (___ WPM).	QSM	Shall I repeat the last message which I sent you, or some previous message? Repeat the last message you sent me [or message(s) number (s) ___].	QTR	What is the correct time? The time is ___.
QRS	Shall I send more slowly? Send more slowly (___ WPM).	QSN	Did you hear me (or ___) on ___ kHz? I did hear you (or ___) on ___ kHz.		
QRT	Shall I stop sending? Stop sending.	QSO	Can you communicate with ___ direct or by relay? I can communicate with ___ direct (or by relay through ___).		
QRU	Have you anything for me? I have nothing for you.	QSP	Will you relay to ___? I will relay to ___.		
		QSU	Shall I send or reply on this frequency (or on ___ kHz)? Send or reply on this frequency (or ___ kHz).		

Special Q signal adopted by ARRL:

QST General call preceding a message addressed to all amateurs and ARRL members.

steadily gaining popularity. This growth has been largely brought about by UHF ATV repeaters, which greatly extend the communications range of an individual ATV station. U.S. and Canadian ATV repeaters are listed in the ARRL *Repeater Directory*.

Because an FSTV signal can occupy as much as 6 MHz, only the 70 cm and higher-frequency bands are wide enough to ac-

commodate this type of operation. Specific ATV channels are designated in the ARRL band plans, which are included in the *Repeater Directory*.

U.S. and Canadian FSTV stations generally follow Electronic Industries Association (EIA) RS-170 standard for black-and-white transmissions and National Television Standards Committee (NTSC) recommendations for color televi-

sion. Amateurs are not limited to using industry standards, but their use assures the compatibility of a wide variety of commercially available TV cameras, sync generators and receiving equipment. Most home TV receivers require only a frequency converter to translate the 70- or 23-cm ATV frequencies to a normal broadcast TV channel. Some UHF-TV tuners can receive 70-cm ATV by retuning broadcast channel

**Table 5**

\*Amateur stations are authorized the following emissions on this band: N0N, A1A, A2A, A2B, A3E, A3C, A3F, F1B, F2B, F3E, G3E, F3C, F3F, H3E, J3E, R3E.

\*\*F8E emissions may also be used in the 902-928 MHz band.

\*PON may also be used on this band.

#### Limitations:

The following list contains those limitations from Section 97.61 considered most important to amateurs in the US. For a complete list of the limitations, see *The FCC Rule Book*.

(1) Novice and Technician class radio operators are limited to the use of international Morse code when communicating in this band.

(2) This band may only be used by Amateur stations in the State of Alaska or within fifty nautical miles of the State of Alaska for emergency communications with other stations authorized to use this band in the State of Alaska. This frequency band is shared with licensees in the Alaska-private fixed service who may use it for certain non-emergency purposes.

(3) Where, in adjacent regions or subregions, a band of frequencies is allocated to different services of the same category, the basic principle is the equality of right to operate. Accordingly, the stations of each service in one region or subregion must operate so as to not cause harmful interference to services in the other regions or subregions. (See International Telecommunication Union Radio Regulations, RR 346 [Geneva, 1979].)

(4) This band is allocated to the amateur, fixed and mobile services in the United States on a co-primary basis. The basic principle which applies is the equality of right to operate. Amateur, fixed and mobile stations must operate so as not to cause harmful interference to each other.

(5) Amateur stations in the 1900-2000 kHz, 220-225 MHz, 420-450 MHz, 902-928 MHz, 1240-1300 MHz, 2300-2310 MHz, 2390-2450 MHz, 3.3-3.5 GHz, 5.650-5.925 GHz, 10.0-10.5 GHz, 24.05-24.25 GHz, 76-81 GHz, 144-149 GHz and 241-248 GHz bands must not cause harmful interference to stations in the Government radiolocation service and are not protected from interference due to the operation of stations in the Government radiolocation service.

(6) No amateur station shall operate north of Line A (see § 97.3(j)) in the 420-430 MHz band.

(7) The 420-430 MHz band is allocated to the Amateur service in the United States on a secondary basis, but is allocated to the fixed and mobile (except aeronautical mobile) services in the International Table of Allocations on a primary basis. Therefore, amateur stations in this band must not cause harmful interference to stations authorized by other nations in the fixed and mobile (except aeronautical mobile) services and are not protected from interference due to the operation of stations authorized by other nations in the fixed and mobile (except aeronautical mobile) services.

(8) In the 902-928 MHz band, amateur stations shall not operate within the States of Colorado and Wyoming, bounded by the area of: latitude 39° N to 42° N, and longitude 103° W to 108° W. This band is allocated on a secondary basis to the Amateur Service subject to not causing harmful interference to the operations of Government stations authorized in this band or to Automatic Vehicle Monitoring (AVM) systems. Stations in the Amateur service are not protected from any interference due to the operation of industrial, scientific and medical (ISM) devices, AVM systems or Government stations authorized in this band.

(9) In the 902-928 MHz band, amateur stations shall not operate in those portions of the States of Texas and New Mexico bounded on the south by latitude 31° 41' N, on the east by longitude 104° 11' W, on the north by latitude 34° 30' N, and on the west by longitude 107° 30' W.

(10) The 430-440 MHz band is allocated to the Amateur service on a secondary basis in ITU Regions 2 and 3. Amateur stations in this band in ITU Regions 2 and 3 must not cause harmful interference to stations authorized by other nations in the radiolocation service and are not protected from interference due to the operation of stations authorized by other nations in the radiolocation service. In ITU Region 1 the 430-440 MHz band is allocated to the Amateur service on a co-primary basis with the radiolocation service. As between these two services in this band in Region 1 the basic principle which applies is the equality of right to operate. Amateur stations authorized by the United States and radiolocation stations authorized by other nations in Region 1 must operate so as not to cause harmful interference to each other.

(11) In the 1240-1260 MHz band amateur stations must not cause harmful interference to stations authorized by other nations in the radionavigation-satellite service and are not protected from interference due to the operation of stations authorized by other nations in the radionavigation-satellite service.

(12) In the United States, the 2300-2310 MHz band is allocated to the Amateur service on a co-secondary basis with the Government fixed and mobile services. In this band, the fixed and mobile services must not cause harmful interference to the Amateur service.

(13) In the 2300-2310 MHz and 2390-2450 MHz band, the Amateur service is allocated on a secondary basis in all ITU Regions. In ITU Regions 2 and 3, stations in the Amateur service must not cause harmful interference to stations authorized by other nations in the fixed, mobile and radiolocation services, and are not protected from interference due to the operation of stations authorized by other nations in the fixed, mobile and radiolocation services.

(14) Amateur stations in the 2400-2450 MHz band are not protected from interference due to the operation of industrial, scientific and medical devices on 2450 MHz.

(15) Amateur stations in the 3.332-3.339 GHz, 3.3458-3.3525 GHz, 119.98-120.02 GHz, 144.68-144.98 GHz, 145.45-145.75 GHz, 146.82-147.12 GHz and 343-348 GHz bands must not cause harmful interference to stations in the radio astronomy service. Amateur stations in the 300-302 GHz, 324-326 GHz, 345-347 GHz, 363-365 GHz and 379-381 GHz bands must not cause harmful interference to stations in the space research service (passive) or Earth exploration-satellite service (passive).

(17) In the United States the 3.3-3.5 GHz band is allocated to the Amateur service on a co-secondary basis with the non-government radiolocation service.

(18) In the 5.650-5.725 GHz band, the Amateur service is allocated in all ITU regions on a co-secondary basis with the space research (deep space) service. In the 5.725-5.850 GHz band the Amateur service is allocated in all ITU regions on a secondary basis. In the 5.650-5.850 GHz band amateur stations must not cause harmful interference to stations authorized by other nations in the radiolocation service, and are not protected from interference due to the operation of stations authorized by other nations in the radiolocation service. In the 5.850-5.925 GHz band the Amateur service is allocated in ITU Region 2 on a co-secondary basis with the radiolocation service. In the 5.850-5.925 GHz band amateur stations must not cause harmful interference to stations authorized by other nations in the fixed, fixed-satellite and mobile services, and are not protected from interference due to the operation of stations authorized by other nations in the fixed, fixed-satellite and mobile services.

(19) In the United States, the 5.850-5.925 GHz band is allocated to the Amateur service on a secondary basis to the non-government fixed-satellite service. In the 5.850-5.925 GHz band amateur stations must not cause harmful interference to stations in the non-government fixed-satellite service and are not protected from interference due to the operation of stations in the non-government fixed-satellite service.

(20) Amateur stations in the 5.725-5.875 GHz band are not protected from interference due to the operation of industrial, scientific and medical devices on 5.8 GHz.

(21) Amateur stations in the 1900-2000 kHz, 10.45-10.50 GHz, 76-81 GHz, 144-149 GHz and 241-248 GHz bands must not cause harmful interference to stations in the non-government radiolocation service and are not protected from interference due to the operation of stations in the non-government radiolocation service.

(22) Amateur stations in the 1240-1300 MHz, 10.0-10.5 GHz, 24.05-24.25 GHz, 76-81 GHz, 144-149 GHz and 241-248 GHz bands must not cause harmful interference to stations authorized by other nations in the radiolocation service and are not protected from interference due to the operation of stations authorized by other nations in the radiolocation service.

(24) In the United States, the 24.05-24.25 GHz band is allocated to the Amateur Service on a co-secondary basis with the non-government radiolocation and Government and non-government Earth

exploration-satellite (active) services.

(25) The 119.98-120.02 GHz band is allocated to the Amateur service on a secondary basis. Amateur stations in this band must not cause harmful interference to stations operating in the fixed, inter-satellite service and mobile services, and are not protected from interference caused by the operation of stations in the fixed, inter-satellite and mobile services.

(26) Amateur stations in the 24.00-24.25 GHz band are not protected from interference due to the operation of industrial, scientific and medical devices on 24.125 GHz.

(27) Amateur stations in the 244-246 GHz band are not protected from interference due to the operation of industrial, scientific and medical devices on 245 GHz.

(28) Amateur stations in the 10100-10150 kHz band must not cause harmful interference to stations authorized by other nations in the fixed service. Amateur stations shall make all necessary adjustments (including termination of transmission) if harmful interference is caused.

(29) Until July 1, 1989, amateur stations in this band must not cause harmful interference to stations authorized by other nations in the fixed and mobile services. Amateur stations must make all necessary adjustments (including termination of transmission) if harmful interference is caused.

(30) Amateur stations in the 449.5-450 MHz band must not cause interference to and are not protected from interference due to the operation of stations in the space operation service, the space research service, or for space telecommand.

(31) In the United States, the 10.0-10.5 GHz band is allocated to the Amateur service on a co-secondary basis with the non-government radiolocation service.

(32) Amateur stations in these bands may be used for communications related to relief operations in connection with natural disasters. See Appendix 6 to this Part.

(33) Novice and Technician class radio operators may not use F1B emissions in this band.

(34) Amateur stations located in Regions 1 and 3, and amateur radio stations located within Region 2 which are west of 130° West longitude may also use A3E, F3E and G3E emissions.

(35) Novice and Technician class radio operators are only permitted to use A1A and J3E emissions from 28300-28500 at a maximum power output of 200 watts.

(36) Novices are permitted all authorized modes from 222.1 to 223.9 MHz at a maximum power output of 25 watts.

(37) Novices are permitted all authorized modes from 1270 to 1295 MHz at a maximum power output of 5 watts.

## Note

The types of emission referred to in the amateur rules are as follows:

Type N0N—Steady, unmodulated pure carrier.

Type A1A—Telegraphy without use of modulating audio frequency.

Type A2A, A2B—Amplitude tone-modulated telephony.

Type A3E—Double-sideband AM telephony.

Type J3E—Single-sideband, suppressed-carrier AM telephony.

Type R3E—Reduced-carrier SSB telephony.

Type H3E—Full-carrier SSB telephony.

Type A3C—Facsimile.

Type A3F—Television.

Type F1B—Frequency-shift telephony.

Type G1B—Phase-shift telephony.

Type F2B—Audio frequency-shift telephony.

Type G2B—Audio phase-shift telephony.

Type F3E—Frequency-modulated telephony.

Type G3E—Phase-modulated telephony.

Type F3C—FM facsimile.

Type G3C—PM facsimile.

Type F3F—FM television.

Type G3F—PM television.

Type P0N—Pulse.

(9, 14, 15)	24,000.000-24,010.000	†
	24,010.000-24,250.000	†

† Amateur stations are authorized the following emissions on this band: A0, A1, A2, A3, A4, A5, F1, F2, F3, F4, F5, P0, P1, P2, P3, P4, P5, P9

## Limitations

1) Phone privileges are restricted to holders of advanced Amateur Radio Operators Certificates, and of Commercial Certificates.

2) Phone privileges are restricted as in footnote 1, and to holders of Amateur Radio Operators Certificates, whose certificates have been endorsed for operation on phone in these bands.

3) Amplitude modulation (A2, A3, A4) shall not exceed  $\pm 3$  kHz (6A3).

4) Frequency modulation (F2, F3, F4) shall not produce a carrier deviation exceeding  $\pm 3$  kHz, (6F3) except that in the 52-54 MHz and 144.148 MHz bands and higher the carrier deviation shall not exceed  $\pm 15$  kHz (30F3).

5) Slow-scan television (A5), permitted by special authorization shall not exceed a bandwidth greater than that occupied by a normal single-sideband voice transmission.

6) Television (A5), permitted by special authorization, shall employ a system of standard interface and scanning with a bandwidth of not more than 4 MHz.

7) Pulse modulation with any mode of transmission shall not produce signals of a bandwidth exceeding 15 kHz.

8) Pulse modulation with any mode of transmission shall not produce signals of a bandwidth exceeding 30 kHz.

9) Any mode may be used.

10) Packet transmissions shall not produce signals exceeding 10 kHz.

11) Packet transmissions shall not produce signals exceeding 25 kHz.

12) Packet transmissions shall not produce signals exceeding 100 kHz.

13) Licensees performing an Amateur Experimental Service may use such modulation techniques or types of emission for packet transmission as they may select by experimentation on conditions that they do not exceed the bandwidths established in 10, 11 and 12.

14) Only packet transmissions shall be used.

15) Final RF output power used for packet transmissions shall not exceed 100 watts peak power and 10 watts average power.

16) On 17 meters and 12 meters, all emissions may have a maximum bandwidth of 6 kHz. Holders of Amateur Radio Operators Certificates may use A1 or F1 emissions only. Holders of advanced Amateur Radio Operators Certificates may use all authorized modes.

Operation in frequency band 1.800-2.000 MHz shall be limited to the area as indicated in the following table and shall be limited to the indicated maximum dc power input to the anode of the final radio frequency stage of the transmitter during day and night hours respectively; for the purpose of this table "day" means the hours between sunrise and sunset, and "night" means the hours between sunset and sunrise. A1, A3, and F3 emissions are permitted.

D 1.875-1.900 MHz	H 1.975-2.000 MHz

## Power Level—Watts

0—Operation not permitted
1— 25 night 125 day
2— 50 night 250 day
3—100 night 500 day

\*At presstime there was no official word on the implementation of the new WARC emissions designators, but we understand that the Department of Communications has the matter under consideration.

P5 — Excellent

P4 — Good

P3 — Fair

P2 — Poor

P1 — Barely perceptible

ATV picture quality reporting system.

14, possibly with slight modification. Some of the newer "cable-ready" TV receivers and video cassette recorders (VCRs) have wide-range tuners that can tune to channels in the 70-cm amateur band.

As of June 15, 1983, the FCC discontinued the requirement for FSTV stations to identify by CW or voice, thus permitting FSTV stations to identify by video. Please note that this applies only to transmissions employing U.S. 525-line standards, legally "those which conform, at a minimum, to the monochrome transmission standards of Section 73.682(a)(6) through Section 73.682(a)(13), inclusive (with the exception of Section 73.682(a)(9)(iii) and Section 73.682(a)(9)(iv)." The FCC also requires that the characters be "readily legible." It follows that ATV operators should use an ordinary type style for identification and make their call signs cover enough of the screen to be readable even under weak-signal conditions.

The RST signal reporting system used for CW and phone was not designed for images. Instead, ATVers report picture quality by the letter P followed by a single digit, as follows: 1-barely perceptible, 2-poor, 3-fair, 4-good, and 5-excellent. Some ATV operators make a permanent still-photograph or video-tape record of received pictures for their station log and to mail to the transmitting station.

An off-air monitor is a handy station accessory to have. It will help you judge picture modulation as well as let you know when there is a malfunction.

#### Slow-Scan Television Operating

The popularity of SSTV is rising as a result of increased availability of equipment, some of which can transmit and receive color pictures. The slow-scan technique permits the video signal to be transmitted in a normal voice bandwidth. This makes it possible to use the HF amateur bands for SSTV. Popular frequencies for SSTV operation are:

U.S. SSTV		IARU Region 1
Freq. (kHz)	License	(Europe/Africa) Freq. (kHz)
3845	General	3730-3740
7171	Advanced	7035-7045
14,230	General	14,225-14,235
21,340	General	21,335-21,345
28,680	General	28,675-28,685

Before transmitting, first listen around the calling frequencies, then either respond on voice to a station calling CQ SSTV or call CQ SSTV yourself after ascertaining that the frequency is not in use. Call in the following manner: "CQ SSTV CQ SSTV CQ SSTV this is W9NTP W9NTP W9NTP over." Once voice contact is established and it is clear to both stations which SSTV standard is being used, the video transmission can start. You should identify your video as you start your transmission and as you end transmission of video as follows: "W9NTP this is W0LMD, video follows. (SSTV pictures sent). Okay, how

do you like that one? W9NTP this is W0LMD over."

When you are operating SSTV, be sure to carefully monitor your transmissions to make sure your signal does not exceed normal voice bandwidth limitations.

SSTV signals can be stored on audio cassette tape. It's nice to be able to play back a rare SSTV DX QSO to visitors in your shack when there is no on-the-air SSTV activity to demonstrate.

#### Digital Communications Procedures

Baudot radioteletype (RTTY) has been a regular part of Amateur Radio since the late 1940s. Federal Communications Commission (FCC) rules now permit three specified codes on any frequency where digital communication is permitted. These three specified codes are: ITA2 (Baudot/Murray), the American National Standard Code for Information Interchange (ASCII) and CCIR 476-2 and 476-3, also known as Amateur Teleprinting Over Radio (AMTOR). Above 50 MHz, any digital code is permitted. For a detailed discussion of these codes see Chapter 19.

#### Frequencies

On the HF bands, the digital communications (RTTY) frequencies are usually found at the top of the CW portion of each band. Traditionally, the 20-meter RTTY subband has received the heaviest use during daylight hours; the vicinity of 3.6 MHz is active at night. The increased popularity of RTTY has brought about increased use of the 40-meter RTTY subband. See the Radio-Frequency Allocations Tables in this chapter for a list of bands where RTTY is authorized. Suggested operating frequencies for RTTY are:

U.S. RTTY Frequencies (kHz)	IARU Region 1 (Europe/Africa) Band Plan (kHz)
3590 RTTY DX	3580-3620
3610-3630	
7040 RTTY DX	7035-7045
7080-7100	
10,140-10,150	10,140-10,150
14,075-14,100	14,080-14,100
18,100-18,110*	18,100-18,110
21,090-21,100	21,080-21,120
24,920-24,930	24,920-24,930
28,090-28,100	28,050-28,150

\*Pending FCC approval for U.S. amateur use.

#### Station Identification

FCC rules permit identification of a digital communication station in the digital code used for communication when ITA2, AMTOR or ASCII are used, and also by Morse code or voice (where radiotelephone is permitted). Above 50 MHz when using other digital codes, identification must be by one of the methods just mentioned.

#### ITA2 Operation

ITA2 (Baudot/Murray) has been the predominant RTTY code used by amateurs. It became popular because of the

availability of inexpensive, surplus teleprinters that use 5-unit code and operate at speeds of 60, 67, 75 or 100 WPM, corresponding to 45, 50, 56 and 75 bauds, respectively. Gradually, starting in the late 1970s, these mechanical teleprinters were replaced with computer-based systems. Some of these systems are based on personal computers programmed for ASCII-ITA2 code conversion. Others are commercially designed electronic RTTY terminals.

When transmitting via ITA2, you are usually in control of the receiving station's copy format. Because of the variety of mechanical and electronic devices in use, your message may be displayed on a video-display terminal (VDT) or a printer.

At the beginning of each transmission, it is desirable to make sure that the receiving station's printer or video display is set to the first printing position of a new line and in letters case. This can be done by sending two carriage returns (2CR), a line feed (LF), and a letters (LTRS) function. This 2CR LF LTRS combination is also used as an end-of-line (EOL) sequence whenever you wish to begin a new line. While only one CR is needed for newer printers, two CRs are necessary for older teleprinters to give their massive carriages enough time to return to the first printing position of the line. Only one LF is sent to conserve the receiving station's supply of printer paper. The LTRS function ensures that the printer is in letters case.

For years, RTTY operators were accustomed to teleprinters which could print up to 72 characters per line. It is no longer that simple. There are video display terminals (VDTs) and personal computers which may display from 20 to 80 characters per line, sometimes as many as 132. Printers are available with anywhere from 40 to 132 characters per line. So it is difficult to know how many characters to type per line and still have it fit the other station's screen or printer format. If you know that the other station is using a printer or VDT with 40 characters per line, you can keep that in mind when you type. However, as a general rule for normal teleprinter-to-teleprinter communication, it is desirable not to exceed 69 characters per line, the CCITT standard for both printers and video displays.

Some VDTs and printers automatically go to the first printing position of the new line when the previous line is full. This feature may be called *automatic new line* or *wrap around*. Not all mechanical printers have this feature, however. When they don't, characters can pile up at the end of the line and not be readable. To accommodate the older printers, an end-of-line sequence of 2CR LF LTRS must be sent at the end of each line.

When you are typing, precede all figures-case characters with a FIGS function. After finishing the figures-case characters, be sure to return to letters case by sending LTRS before typing anything else. Some, but not all, teleprinters have a feature known as "unshift on space" which automatically inserts a LTRS function upon

receipt of a space function. This feature can be a blessing at times but also can be a nuisance when printing a page full of numbers. To be positive that the different display equipment will print your figures correctly, it is good practice to precede each number group with a FIGS function and include a LTRS function when shifting to the letters case.

At the end of each transmission, it is considered courteous to transmit an end-of-line sequence (2CR LF LTRS) so that both stations' printers will start the next transmission on a new line and in letters case.

In ITA2, it is safe to assume that all the letters-case characters will print correctly on the other station's printer or display. This is not necessarily true of the figures-case characters, particularly for FIGS D, F, G, H and J, which are subject to national variation. The teleprinters which many U.S. amateurs have used also differs from ITA2 for FIGS V and Z. Avoid these figures-case characters when talking to DX RTTY stations. A few stations are using teleprinters with weather symbols in figures case. If you want to play it safe, avoid figures-case characters by spelling out most punctuation, using figures case only for numbers, period and slant.

ITA2 has a limited character set that provides only capital letters. Unlike ASCII, which has a variety of control characters, ITA2 has only a few machine functions: space, carriage return, line feed, figures, letters and blank. Because of the lack of control characters, commercial and government services have evolved a number of sequences of combinations used for special purposes. Some of these sequences have found their way into Amateur Radio RTTY. One that you may have seen is NNNN, which is an end-of-message signal. Another that has appeared on the ham bands is ZCZC, the start-of-message signal. Both of these sequences are from CCITT Recommendation S.4, which lists some others that you could encounter sometime:

CCCC	for remotely switching on a reperforator or equivalent device
SSSS	for remotely switching on a terminal
FFFF	for remotely turning off a reperforator
KKKK	ready-for-test signal
KLKL	for remotely switching on a reader
XXXXX	error signal

When RTTY equipment is tested, lines of RY sequences are sometimes used. The RY sequence is excellent for exercising mechanical teleprinters because R and Y have complementary bit patterns, causing most mechanical parts to move each character. However, it does not test to see whether every different character can be printed. For that purpose, many RTTY operators use a test message text such as one of the following:

THE QUICK BROWN FOX JUMPS  
OVER THE LAZY DOG 1234567890

VOYEZ LE BRICK GEANT QUE  
J'EXAMINE PRES DU WHARF  
1234567890

In most other respects ITA2 RTTY procedure is similar to that used on CW. All the CW abbreviations and Q signals are used.

### AMTOR Operation

For a technical overview of AMTOR, see Chapter 19. The basic reason for using AMTOR in preference to ITA2 is that AMTOR has error-reduction features.

At the moment, most AMTOR activity is around 14,075 and 3637.5 kHz, which are used as calling frequencies. Operators usually move off the calling frequency to free it for others. However, there are some automatically controlled stations that just stay on these frequencies. At this writing, automatic control of an AMTOR station in the U.S. requires an FCC Special Temporary Authority.

In most respects, AMTOR operation is the same as for ITA2. However, AMTOR has several modes of operation.

In Mode A, the transmitting station sends groups of three characters. If a group is received correctly, the receiving station acknowledges, and the transmitting station sends the next three. If the receiving station does not acknowledge, the transmitting station keeps sending the three characters until acknowledged. This system is known as Automatic Repeat Request (ARQ) and is limited to contacts between two stations.

Mode B employs Forward Error Correction (FEC). Collective Mode B is used to transmit to more than one station, as in a CQ, bulletin transmission, or when talking to a net. Selective Mode B uses FEC but is intended for a single station or perhaps a group of stations.

### ASCII Operation

ASCII operation differs from ITA2 operation in that it has a larger character set. Besides a number of control characters, ASCII also provides both upper- and lower-case letters and a more complete set of punctuation marks.

ASCII does away with letters and figures cases that sometimes cause ITA2 characters to print in the wrong case. ASCII is a character set that was designed for both computer and data communications uses.

Because of newer printers and elimination of the LTRS/FIGS problem, only CR LF need be sent as an end-of-line sequence. There are other ASCII *format effectors* (control signals which effect where print occurs on the page) if you want to make use of its entire capability. There are also control characters for start of message, start of text, device control, etc. which may be part of a communications protocol.

To take advantage of the expanded character set, ASCII test messages could be as follows:

ThE QuicK BrowN FoX JumpS Over ThE  
LazY Dog 1234567890  
VoyeZ Le BricK GeanT QuE J'Examine  
PreS Du WharF 1234567890

When ASCII is used, it is possible that the way a transmitting station formats a message will not be the way that the message is presented to the receiving operator. Computer-based systems may be used to provide split-screen displays, simply file messages away for later use, or process incoming messages according to an agreed protocol.

### Packet-Radio Protocols

From a user's viewpoint, the above information about ASCII operation also applies to packet radio. However, in packet radio, there are seven different protocol layers, as outlined in Chapter 19. The Application and Presentation Layers affect what the operator sees on a VDT or printer, depending on the design of the software. However, the Physical, Link and Network layers govern what is sent on the air. Although there is some standardization at the lower protocol layers, revolutionary changes are expected in packet-radio protocol development over the years ahead.

The use of the RTTY subbands is encouraged for routine packet operations on all HF bands. The frequencies listed below are exceptions to this general rule to provide usable channels for automatic message forwarding:

3594.3 kHz	Intercontinental message forwarding
3607.3 kHz	North American message forwarding
7038.3 kHz	Intercontinental message forwarding
7091.3 kHz	North American message forwarding
10145.3 kHz	Intercontinental message forwarding
10147.3 kHz	North American message forwarding
Note: These frequencies are subject to noninterference with fixed stations outside the United States.	
14102.3 kHz	Intercontinental message forwarding (experimental)
14108.3 kHz	Intracontinental message forwarding (experimental)

Note: The lowest frequency provides sufficient protection to receivers using CW bandwidths to receive 14100-kHz beacons.

The frequencies listed below conform to the RTTY subbands and are suggested for automatic message forwarding when propagation is favorable.

1802.3 kHz	
18106.3 and 18108.3 kHz	(pending FCC approval)
21096.3 and 21098.3 kHz	
24926.3 and 24928.3 kHz	
28102.3 and 28104.3 kHz	

Note: These 28-MHz frequencies may be considered for both automatic message forwarding and network entry points for Novices and Technicians.

For more information, see Moved and Seconded, Sept. 1987 QST, p. 54.

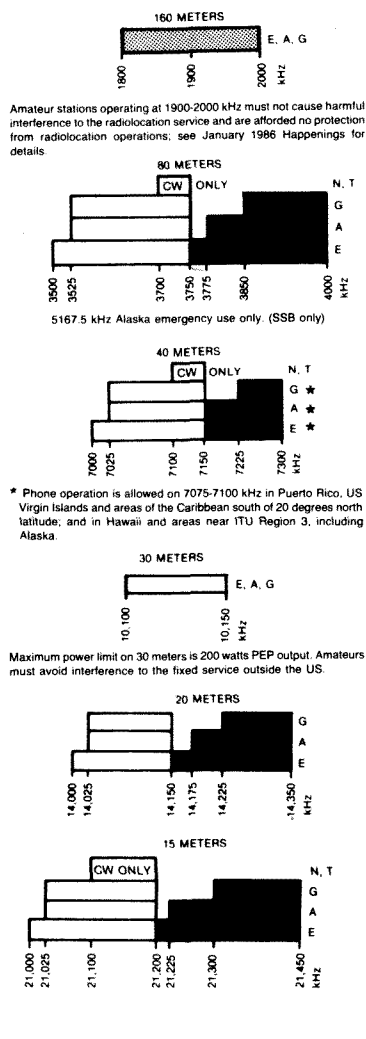

### Computer-Based Message Systems

Since the mid 1970s, a number of Computer-Based Message Systems (CBMSs) have appeared on the ham bands. Possibly you have heard them called MSO (Message Storage Operation), bulletin board or mailbox. They will automatically respond to calls on their operating frequency if the calling station uses the correct character sequence. A remote station can write messages to be stored in the system. Stations can subsequently read remotely entered messages plus any bulletin messages.

Message handling in this manner is third-party traffic, and the system operator

## US AMATEUR SUBBAND ALLOCATIONS, 1.8 to 1300 MHz

At all times, transmitter power should be kept down to that necessary to carry out the desired communications. Power is rated in watts PEP output. Unless otherwise stated, the maximum power output is 1500 W. Power for all license classes is limited to 200 W in the 10,100-10,150 kHz band and in all Novice subbands below 28,100 kHz. Novices and Technicians are restricted to 200 W in the 28,100-28,500 kHz subband. In addition, Novices are restricted to 25 W in the 222.1-223.91 MHz subband and 5 W in the 1270-1295 MHz subband.

(SYSOP) is required to observe appropriate rules concerning message content. Also the SYSOP is responsible for maintaining control of the transmitter and removing it from the air in the event of malfunction.

### Working DX

Most amateurs at one time or another make working DX a major aim. As in every other phase of amateur operating, there are right and wrong ways to go about getting best results in working foreign stations. This section will outline a few of them.

The ham who has trouble contacting DX stations readily may find that poor transmitter efficiency is not the reason. He may find that his sending is poor, his call ill-timed, or his judgment in error. Working DX requires the know-how that comes with experience. If you just call CQ DX you may get a call from a foreign station, but it isn't likely to be a "rare one." On the other hand, unless you are

experienced enough to know that conditions are right, your receiver is sensitive and selective enough, and your transmitter and antenna properly tuned and oriented, you may get no calls at all and succeed only in causing some unnecessary QRM.

The call CQ DX means slightly different things to amateurs on different bands:

a) On VHF, CQ DX is a general call ordinarily used only when the band is open, under favorable propagation conditions. For VHF work, such a call is used for looking for new states, countries and grid squares, as well as for distances beyond the customary "line-of-sight" range on most VHF bands.

b) CQ DX on our HF bands may be taken to mean "general call to any foreign station." The term "foreign station" usually refers to any station on a different continent. If you do call CQ DX, remember that it implies you will answer any DX station that calls. If you don't

mean "general call to any DX station," then listen and call the station you do want.

### Codes and Ethics

One of the most effective ways to work DX is to know the operating habits of the DX stations sought, and to abide by the procedures they use. Know when and where to call, and for how long, and when to remain silent while awaiting your chance. DXing has certain understood codes of ethics and procedures that will make this popular amateur pursuit more fun for everybody if everybody follows them. One of the sad things about DXing is to listen to some of the abuse that goes on, mostly by stations on "this" side, as they trample on each other trying to raise their quarry. DX stations have been known to go off the air in disgust at some of the tactics. If W and VE stations will use the procedure in the "DX Operating Code" detailed elsewhere on these pages, we can all make a good impression on the air.

### Snagging the Rare Ones

Once in a while a CQ DX will result in snagging a rare DX contact, if you're lucky. This seldom happens, however; usually, what you have to do is listen — and listen — and then listen some more. If everybody transmits, nobody is going to hear anything. Be a snooper. Usually, unless you are lucky enough to be among the first to hear him, a rare DX station will be found under a pileup, with stations swarming all over him like worker bees over a queen. The bedlam will subside when the DX station is transmitting (although some stations keep right on calling him), and you can hear him. Don't immediately join the pack; be a little cagey. Listen a while, get an idea of his habits, find out where he is listening (if not on his exact frequency), bide your time, and await your chance.

Make your calls short, snappy and distinct. No need to repeat his call (he knows it very well; all he needs to know is that you are calling him), but send your own call a couple of times. Try to find a time when few stations are calling him and he is not transmitting; then get in there! With experience, you'll learn all kinds of tricks, some of them clever, some just plain dirty. You'll have no trouble discerning which is which. Learn to use the clever ones, and shun the dirty ones.

### Choosing Your Band

If it does nothing else in furthering your education, striving to work DX will certainly teach you a few things about propagation. You will find that four principal factors determine propagation characteristics: (1) the frequency band on which you do your operating, (2) the time of day or night, (3) the season of the year and (4) the sunspot cycle. For example, the 3.5- to 4.0-MHz band at high noon in the summertime at the peak of the sunspot cycle is the poorest possible choice, while the same band at midnight during the wintertime at

**Table 7**

### The R-S-T System

#### Readability

- 1 — Unreadable
- 2 — Barely readable, occasional words distinguishable.
- 3 — Readable with considerable difficulty.
- 4 — Readable with practically no difficulty.
- 5 — Perfectly readable.

#### Signal Strength

- 1 — Faint signals, barely perceptible.
- 2 — Very weak signals.
- 3 — Weak signals.
- 4 — Fair signals.
- 5 — Fairly good signals.
- 6 — Good signals.
- 7 — Moderately strong signals.
- 8 — Strong signals.
- 9 — Extremely strong signals.

#### Tone

- 1 — Sixty-cycle ac or less, very rough and broad.
- 2 — Very rough ac, very harsh and broad.
- 3 — Rough ac tone, rectified but not filtered.
- 4 — Rough note, some trace of filtering.
- 5 — Filtered rectified ac but strongly ripple-modulated.
- 6 — Filtered tone, definite trace of ripple modulation.
- 7 — Near pure tone, trace of ripple modulation.
- 8 — Near perfect tone, slight trace of modulation.
- 9 — Perfect tone, no trace of ripple or modulation of any kind.

If the signal has the characteristic steadiness of crystal control, add the letter x to the RST report. If there is a chirp, the letter c may be added to so indicate. Similarly for a click, add k. See FCC Regulations 97.73, purity of emissions. This reporting system is used on both CW and voice, except that the "tone" report is left out on voice.

the low part of the cycle might produce some very exciting DX. Similarly, you will learn by experience when to operate on which band for the best DX by juggling these factors using both long-range and other indication of band conditions. WWV transmissions can also be helpful in indicating both current and immediate-forecast band conditions.

On some bands, such as 10 and 6 meters, beacons have been established to give an indication of band openings. Listen between 28.2 and 28.3 MHz on 10 meters and around 50.110 MHz on 6 meters. Commercial stations near ham-band edges are also a fair indication of openings. But remember that many of these run many times the maximum amateur power, and consequently may be heard well before skip improves to the point necessary to sustain amateur communications.

Conditions in the transmission medium often make it possible for the signals from low-powered transmitters to be received at great distances. In general, the higher the frequency band, the less important power considerations become, for occasional DX work. This accounts in part for the relative popularity of the 14-, 21- and 28-MHz bands among amateurs who like to work DX.

### DX Operating Code (for W/VE Amateurs)

If observed by all W/VE amateurs, these suggestions will go a long way toward making DX more enjoyable for everybody.

1) Call DX only after he calls CQ or QRZ?, signs  $\overline{SK}$ , or the phone equivalent.

2) Do not call a DX station:

a) on the frequency of the station he is working until you are sure the QSO is over. This is indicated by the ending signal  $\overline{SK}$  on CW and any indication that the operator is listening, on phone.

b) because you hear someone else calling him.

c) when he signs  $\overline{KN}$ ,  $\overline{AR}$ , CL or phone equivalents.

d) after he calls a directional CQ, unless of course you are in the right direction or area.

3) Keep within your frequency-band limits.

4) Observe calling instructions given by DX stations. 10U means call 10 kHz up from his frequency, 15D means 15 kHz down, etc.

5) Give honest reports. Many stations depend on signal reports for adjustment of station equipment.

6) Keep your signal clean. Key clicks, chirp, hum or splatter give you a bad reputation and may get you a citation from the FCC.

7) Listen for and call the station you want. Calling CQ DX is not the best assurance that the rare DX will reply.

8) When there are several W or VE stations waiting to work a DX station, avoid asking him to "listen for a friend." Let your friend take his chances with the rest. Also avoid engaging DX stations in rag chews against their wishes.

### Awards

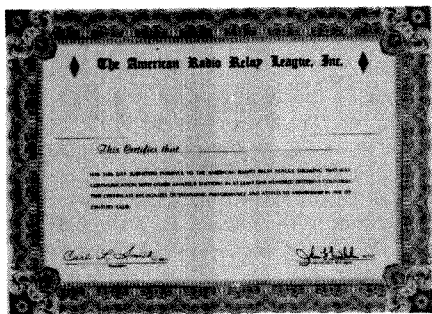

League-sponsored operating activities have useful objectives and provide much enjoyment for members of the fraternity. Achievement in Amateur Radio is also recognized by various awards offered by ARRL. Basic rules require that sufficient funds be included with all submissions of cards to ensure their safe return. A basic fee schedule for return postage is included with each award application. Applicants in the U.S., its possessions and Canada must be ARRL members to participate in the WAS and DXCC programs. DX stations are exempted from this requirement.

### DX Century Club Award

The DXCC is one of the most popular and sought-after awards in all of Amateur Radio, and among the more difficult to acquire. Its issuance is carefully supervised at ARRL Hq.

To obtain DXCC, an amateur must make two-way contact with 100 "countries" on the ARRL DXCC list. Written confirmations are required for proof of contact. These must show clearly your call sign, and the date, time, frequency and mode. Such confirmations must be sent to ARRL Hq., where each one is carefully scrutinized to make sure it actually con-

firms a contact with the applying amateur, that it is not altered, and that the "country" claimed is actually on the ARRL list. Further safeguards are applied to maintain the high standards of this award. A handsome, king-size certificate and DXCC lapel pin are sent to each amateur qualifying.

The term "country" for DXCC purposes does not necessarily agree with the dictionary definition. Many bodies of land not having independent status politically are classified as countries. For example, the states of Alaska and Hawaii are considered "countries" because of their distance from the U.S. mainland. There are over 300 such designations on the ARRL DXCC list. Once a basic DXCC is issued, the certificate can be endorsed, by sticker, for additional countries by sending the additional cards to ARRL Hq. for checking. Separate DXCC awards are available for mixed modes, all phone, all CW, RTTY, 160 meters and satellites.

Before applying, familiarize yourself with the rules. Application forms (CD-253) may be obtained from ARRL Hq. Also, the complete ARRL DXCC Countries List, containing the current DXCC countries, along with those countries served by the ARRL Membership Overseas QSL Service, ITU and CQ Zones for each country, third-party agreements, and band/mode check-offs for record keeping, is available from the League for \$1. [Note: By action of the ARRL Board of Directors, 10-MHz confirmations are not creditable for ARRL awards.]

#### Five-Band DXCC

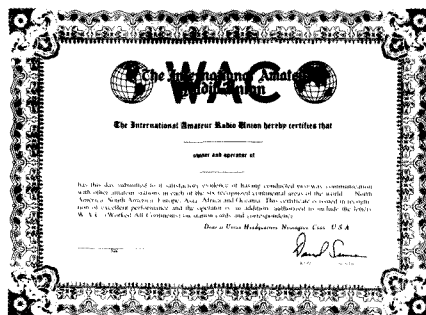

Entirely separate from DXCC, ARRL

also offers a Five-Band DXCC (5BDXCC) Award for those amateurs who submit written proof of having made two-way contact with 100 or more countries on each of five bands since January 1, 1969. For a copy of the complete rules, send an s.a.s.e. to ARRL Hq., 225 Main St., Newington, CT 06111.

#### WAC Award

The ever-popular Worked All Continents Award (WAC), sponsored by the International Amateur Radio Union (IARU), can be yours by simply submitting proof of contact with each of the six continents. Two-way confirmed contacts must be made with amateurs in each of six continental areas of the world: Africa, Asia, Europe, North America, Oceania and South America. Certificates are available for the following: Basic award, CW, phone, SSTV, RTTY, FAX, satellite and 5-band. Endorsement stickers are available for these achievements: 6-band (for 5-band awards), QRP (5-W output or less), 1.8 MHz, 3.5 MHz, 50 MHz, 144 MHz and 430 MHz. Contacts on 10, 18 and 24 MHz are void for the 5-band certificate and 6-band sticker. Confirmations must be submitted for any awards claimed.

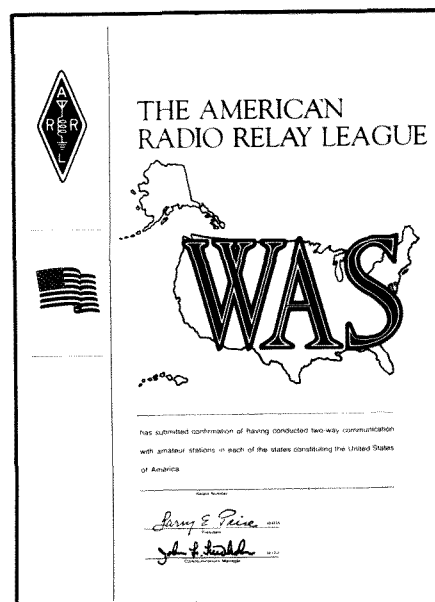

Amateurs residing in the USA or its possessions may obtain full details about the WAC Awards from ARRL Hq. QSLs (not copies) must be sent to ARRL Hq. for checking. ARRL membership is required of all US applicants. Applicants in other countries must send QSLs to their IARU amateur society. That society will certify their eligibility to the IARU Secretariat (ARRL) for issuance of the award on behalf of the Union. Applicants in countries not belonging to the IARU may send their QSLs direct to ARRL Hq. for checking.

#### WAS Award

"WAS" means Worked All States. This award is offered to any amateur who contacts and receives a QSL from each U.S. state. Contacts may be made over any period of time on any or all amateur bands.

Endorsements to the basic award are available for WAS on CW, SSB, Novice, QRP and any single band. Specialty awards (numbered separately) are available for

OSCAR, satellite, SSTV, RTTY, 432 MHz, 220 MHz, 144 MHz, 50 MHz and 160 meters. Confirmations must clearly state that contact took place under the circumstances of the desired endorsement or specialty award.

Complete rules and application forms (MCS-217) are available from ARRL Hq. for an s.a.s.e. Confirmations and application forms may be submitted to an ARRL Special Service Club HF Awards Manager for verification. You can find out the name of the nearest awards manager from ARRL Hq. If you cannot find an awards manager in your area, you may send your cards and application to ARRL Hq. for checking. Be sure to include sufficient postage for their safe return.

#### 5BWAS Awards

A handsome certificate will be issued to all amateurs who submit original proof of contact with all 50 states on each of five amateur bands, made after January 1, 1970 (only contacts made after that day will be eligible). Rules require applicants in the U.S., its possessions and Canada to be ARRL full members. Standard WAS rules apply. Write to ARRL Hq. for the application, rules and postage fees for the return of your cards.

#### VUCC

The VHF/UHF Century Club, VUCC, is an ARRL-sponsored achievement award for working grid squares measuring 2° longitude by 1° latitude on frequencies above 50 MHz. Individual awards are issued per band, with initial qualifying levels as follows: 50 MHz — 100; 144 MHz — 100; 220 MHz — 50; 432 MHz — 50; 902 MHz — 25; 1296 MHz — 25; 2.3 GHz — 10; 3.4 GHz — 5; 5.7 GHz — 5; 10 GHz — 5. Each award is endorsable in increments of 25 for 50 and 144 MHz, 10 for 220 and 432 MHz, and 5 for 902 MHz and above. Certificates offered for 220 and 432

### Old Timers Club

If you held an Amateur Radio license 20 or more years ago and are licensed at the present time, you are eligible to become a member of the Old Timers Club. Lapses in activity during intervening years are permitted. An s.a.s.e. (business size, at least 10 x 4 inches) will expedite your certificate.

### Rag Chewers Club

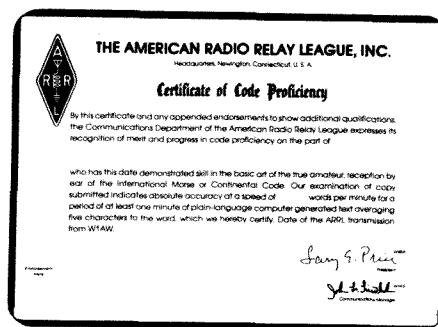

Your first contact as a licensed amateur may very well earn your first award. The Rag Chewers Club is designed to encourage friendly contacts and discourage the "contest" type of QSO with nothing more than an exchange of calls, signal reports and so on. It furthers fraternalism through Amateur Radio.

Membership certificates are awarded to amateurs who report a fraternal-type contact with another amateur lasting a half hour or longer. This does not mean a half hour spent trying to work a rare DX station, but a solid half hour of pleasant "visiting" with another amateur, discussing subjects of mutual interest. If you nominate someone for RCC, please send the information to the nominee who will (in turn) apply to ARRL Hq. for membership. Or if you know you qualify for the RCC, just report the conversation to ARRL Hq. (c/o RCC) and back will come your membership certificate. An s.a.s.e. is appreciated when requesting this award.

### Code Proficiency Award

The Code Proficiency Award permits each amateur to prove himself as a proficient CW operator, and sets up a system of achievement for code skill. It enables

every amateur to check individual code proficiency, to better that proficiency, and to receive a certification of receiving speed.

This program is a lot of fun. The League will award a certificate to any interested individual who demonstrates perfect copy for at least one minute, plain-language. Continental code at 10, 15, 20, 25, 30 or 35 words per minute, as transmitted twice monthly from W1AW and once a month from W6OWP. Special 40-WPM qualifying runs are sent by W1AW in February, June and October and by W6OWP in April, August and December. Neither an amateur license nor ARRL membership is required to participate.

As part of the ARRL Code Proficiency program, W1AW transmits plain-language practice material several times daily at speeds from 5 to 35 WPM, occasionally in reverse order. All amateurs are invited to use these transmissions to increase their code-copying ability. Nonamateurs are invited to utilize the lower speeds, 5, 7½ and 10 WPM, which are transmitted for the benefit of persons studying the code in preparation for the amateur license examination. Check the W1AW material in this chapter or refer to QST for details.

### Contesting

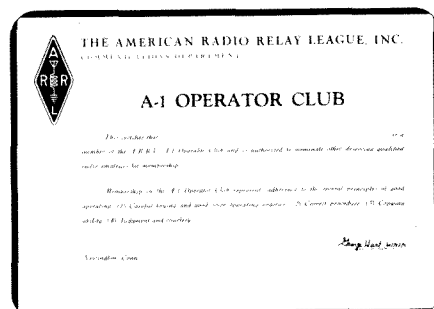

Contesting is to Amateur Radio what the Olympic Games are to worldwide amateur athletic competition: a showcase to display talent and learned skills, as well as a stimulus for further achievement through competition. Increased operating skills and greater station efficiency are the predominant end results of Amateur Radio contesting, whether the operator is a serious contender or a casual participant.

Don't believe it? Tune across the band, any band, and listen for the most efficient operators. Chances are better than even that they are avid contesters or at least have contesting as one of their favorite Amateur Radio activities. How can one tell who is a contester just by listening to a particular operator's style? It is easier to tell who is not interested in contesting by listening. The contester is not likely to be the one, who (while thousands on the frequency are gnashing their teeth in anger) asks the operator of the rarest DXpedition in two decades what the weather is like in "Lower Slobbovia." The contester is not likely to

MHz indicate membership in the Half Century Club; for higher frequencies, the Quarter Century Club is appropriate. Only contacts made on January 1, 1983 and after count for VUCC. QSL cards are certified by an approved ARRL VHF Awards Manager. Please send ARRL Hq. an s.a.s.e. for complete application materials.

### A-1 Operator Club

The A-1 Operator Club should include in its ranks every good operator. To become a member one must be nominated by two persons who already belong. General keying (not speed) or voice technique, procedure, copying ability, judgment and courtesy all count in the rating of candidates under the club rules. Aim to make yourself a fine operator and one of these days you will be pleasantly surprised when your letter carrier arrives at your QTH with your certificate of membership in the A-1 Operator Club.

Kurt, NI6W, contests from Santa Ana, California.

Section leaders earn this handsome certificate in the annual Sweepstakes contest. There are similar awards for other contests.

NK7U is none other than former Major League baseball player Joe Rudi. Joe is active on all bands, and particularly enjoys contests, operating from his home in Oregon.

be the operator, who when working a much-sought-after station on one of the many award nets, punctuates his repeating of the needed exchange 37 times with a long series of "uhhs" and assorted other noises for the lack of anything better to say. The contest operator knows from experience that conciseness aids in efficient and courteous operating.

The contest operator is also likely to have one of the better signals on the band — not necessarily the most elaborate station equipment, but a signal enhanced by the most efficient use of station components available. Contest operation encourages optimization of station and operator efficiency.

The ARRL contest program is so diverse that it holds appeal for almost every operator — the beginning contesteer and the old hand, the newest Novice and oldest Extra-Classer, "Top Band" buff and microwave enthusiast.

A thumbnail sketch of many of the contests sponsored by the ARRL follows. Complete entry rules and details appear in *QST*, usually the month before the contest occurs.

#### January

**VHF Sweepstakes.** Premiere VHF operating event. All bands, 50 MHz and up. ARRL affiliated-club competition, based on members' aggregate total scores.

#### February

**Novice Roundup.** Competition geared for the beginning (Novice and Technician) amateur. Increase code speed through operating, work stations needed for WAS, and other achievements. Awards for ARRL Section winners. Fun for all.

**International DX Contest, CW.** W/VE amateurs work the rest of the world for individual section, country and ARRL affiliated club honors; single-band, QRP and multioperator categories also, with many plaques awarded.

#### March

**International DX Contest, Phone.**

#### June

**VHF QSO Party.** One of two VHF QSO parties. This one (and the September party) lends itself to multioperator mountaintop expedition operation. Use all bands above 50 MHz.

**Field Day.** The number one operating event of the year. More than 25,000 participants take to the fields to operate some 1500 emergency stations for informal competition, a score listing in *QST* and an all-around good time. Don't miss this one.

#### July

**IARU HF World Championship.** Worldwide competition. Everybody works everybody else for ITU zone, DXCC country and U.S. state honors. Varying point scale; ITU zones and IARU member-society headquarters stations are scoring multipliers. Some of those hard-to-work DXCC countries turn out for this contest.

#### August

**UHF Contest.** Similar to the VHF contests, but utilizes the bands at 220 MHz and above. Scoring multipliers are grid squares. The UHF bands come alive for this contest weekend.

#### September

**VHF QSO Party.** Second of two VHF QSO parties (also see June).

#### November

**Sweepstakes.** The most prestigious domestic contest. Two weekends (actually separate contests and listings); one weekend for phone and one for CW. Twenty-four-hour time limit on each mode. W and VE operators work each other. ARRL sections are the scoring multipliers. Awards for both high- and low-power ARRL section winners. An ARRL-affiliated club competition highlights the Sweepstakes activity.

#### December

**160-Meter Contest.** A gathering of "top band" enthusiasts. W/VE types work each other and DX stations for contest credit.

**10-Meter Contest.** A 10-meter operator's

dream come true as 28 MHz springs to life and everyone, worldwide, tries to work everyone else for top score (in country, continent and ARRL section) honors.

That's the ARRL contest program in a nutshell. Of course, more detailed rules and descriptions of the awards structure (certificates and plaques awarded to designated top scorers) are announced in *QST* for each of these events. The monthly "Contest Corral" column of *QST* also details the entry rules for many contests other than those sponsored by ARRL, including the very popular state QSO parties and most other major contests.

#### Public Service

Tens of thousands of U.S. amateurs are involved with public service. Where do you fit in? The emergency preparedness and third-party-traffic handling facets of Amateur Radio beckon. There's a place for every ham in the League's Amateur Radio Emergency Service (ARES), an emergency-preparedness group of approximately 25,000 amateurs who have signed up voluntarily to keep Amateur Radio in the forefront of public service operating. The ARRL National Traffic System (NTS) functions as a message-handling network operating 365 days a year for the systematic handling of third-party traffic. Together, ARES and NTS form a major part of the League's extensive volunteer Field Organization.

Also recognized by ARRL as a part of the organized public service effort is the Radio Amateur Civil Emergency Service (RACES), a part of the Amateur Service serving civil defense under a separate subpart of the amateur regulations; the Military Affiliate Radio System (MARS)

## Operating Aids for Public Service

ARRL Hq. makes available the following free operating aids for public service communications:

<i>Public Service Communications Manual</i>	FSD-235
ARRL numbered radiograms	FSD-3
Sample emergency plan	FSD-27
ARES registration form	FSD-98
Amateur message form	FSD-218
Emergency Reference information	FSD-255
Field Organization Brochure	FSD-300

This entire Public Service Package can be obtained by sending a large (9 x 12-inch) envelope with First Class postage for 6 ounces.

sponsored by the armed forces to provide military communications training for amateurs; and the numerous amateur groups organized into nets or monitoring services by individuals, clubs or other amateur entities for public service. The detailed workings of the League's emergency and traffic programs are covered briefly here and in more depth in the *Public Service Communications Manual*, available free from ARRL Hq. (please provide an s.a.s.e.). Additional information can be found in the *ARRL Operating Manual*, a for-sale publication available at your local radio dealer or direct from Hq.

### ARES and NTS — How They Apply to You

As a member of the local ARES group, you'll be training to provide communications at the city or county level. Each group is headed by an ARRL Emergency Coordinator (EC). Most ARES activities are centered on 2-meter FM, so it's advantageous to have your own emergency-powered VHF gear. However, you really don't need any equipment to join; the training and practice are most important. All you really need is an interest in serving your community through Amateur Radio and participation in periodic tests as time permits. These tests run the gamut from serious simulated emergencies to providing communications for parades and walkathons, or conducting a message-handling service at a shopping center during the Christmas season. Many hams have trained with the National Weather Service to become tornado and storm spotters. All of these activities exist, so that when a flood or an ice storm disrupts the community, experienced hams will know exactly what to do.

Becoming involved is as simple as requesting a registration card (FSD-98) from ARRL Hq. and filling it out. These cards are turned over to the local EC, who registers you in the local ARES organization. Should your community not have an EC, why not volunteer yourself? You qualify if you are a licensed amateur of Technician class or higher, an ARRL member, have a sincere interest in public service and a willingness to put in the time

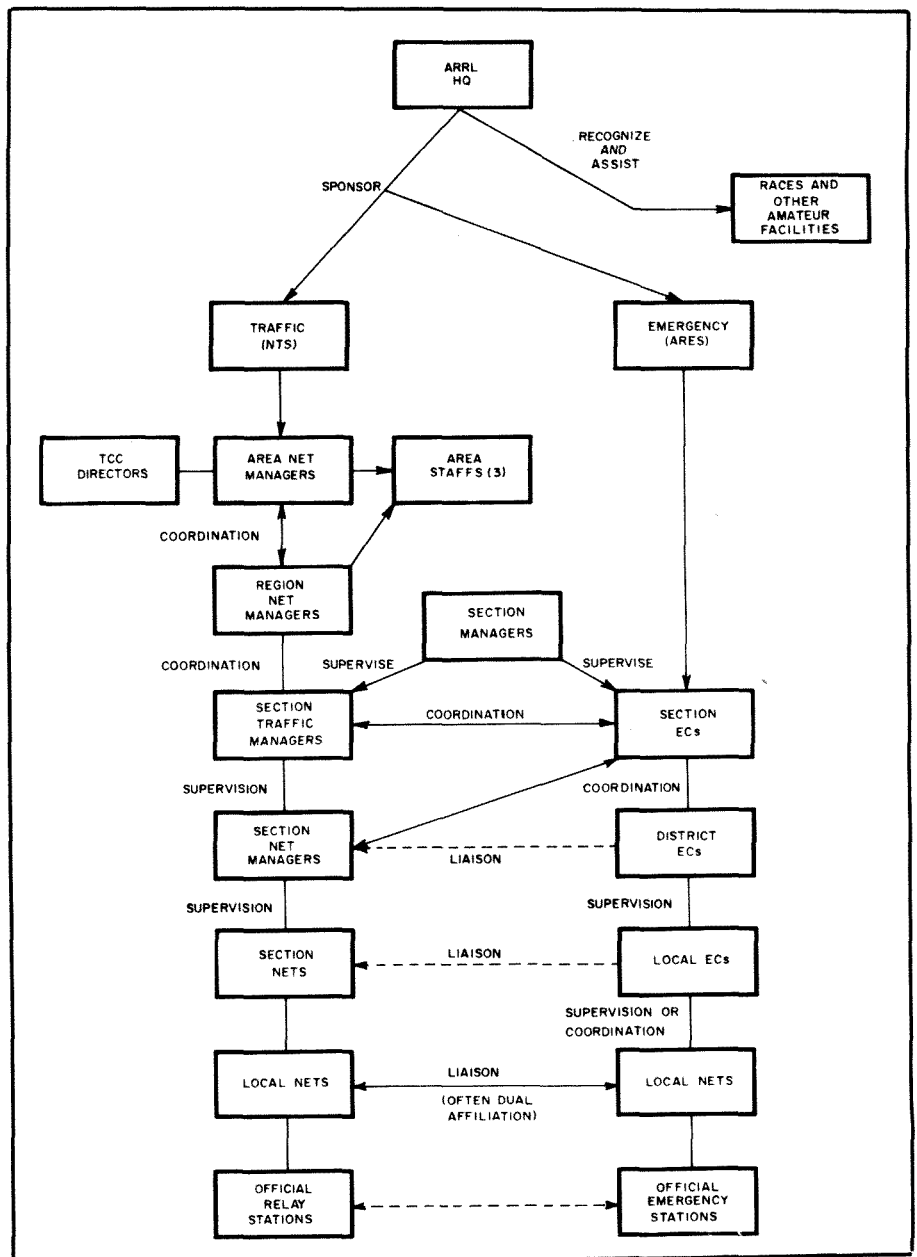

and effort to fulfill the appointment. If this sounds like you, contact your Section Manager — whose name, address and telephone number appear on page 8 of each issue of *QST*.

The bulk of localized emergency communications is handled on VHF. Much involves repeater operation. The reason is simple. Repeaters can be accessed with low-cost and lightweight equipment, hand-held or mobile. Best of all, they provide clear, reliable communications up to 100 miles or so. Many repeaters have emergency-power capabilities as well, making them the mainstay in any widespread emergency.

What's the National Traffic System all about, then? NTS serves a dual purpose: The rapid movement of long-haul traffic from origin to destination and the training of amateur operators in the handling of

formal radiogram traffic in efficient directed nets. A rundown of the NTS schedule of nets and functions can be found in the *Public Service Communications Manual*. In the overview, however, NTS can be visualized as a pony express of the airwaves, with assigned amateurs carrying traffic to and from the next higher (or lower) level in the system. NTS operations are concentrated mainly on the high frequencies (HF), but local nets on 2 meters have become more and more popular as the ideal place to distribute traffic for delivery.

Most ARRL sections have section nets on 80 meters, both phone and CW. You can find the traffic and emergency nets that service your area in the annual *ARRL Net Directory*. Directed net procedures, especially on CW, take a little getting used to, but if you consult the League's

# AMATEUR MESSAGE FORM

Every formal radiogram message originated and handled should contain the following component parts in the order given.

## I PREAMBLE

- Number (begin with 1 each month or year)
- Precedence (R, W, P or EMERGENCY)
- Handling Instructions (optional, see text)
- Station of Origin (first amateur handler)
- Check (number of words/groups in text only)
- Place of Origin (not necessarily location of station of origin)
- Time Filed (optional with originating station)
- Date (must agree with date of time filed)

## II ADDRESS (as complete as possible, include zip code and telephone number)

## III TEXT (limit to 25 words or less, if possible)

## IV SIGNATURE

## CW MESSAGE EXAMPLE

I NR 1 R HXG WIAW 8 NEWINGTON CONN 1830Z July 1  
a b c d e f g h

II DONALD SMITH AA  
164 EAST SIXTH AVE AA  
NORTH RIVER CITY MO 00789 AA  
733 4968 BT

III HAPPY BIRTHDAY X SEE YOU SOON X LOVE BT

IV DIANA AR

Note that X, when used in the text as punctuation, counts as a word.

CW: The prosign AA separates the parts of the address. BT separates the address from the text and the text from the signature. AR marks end of message, this is followed by B if there is another message to follow, by N if this is the only or last message. It is customary to copy the preamble, parts of the address, text and signature on separate lines.

RTTY: Same as CW procedure above, except (1) use extra space between parts of address, instead of AA; (2) omit CW procedure sign BT to separate text from address and signature, using line spaces instead; (3) add a CFM line under the signature, consisting of all names, numerals and unusual words in the message in the order transmitted.

PHONE: Use *prowords* instead of prosigns, but it is not necessary to name each part of the message as you send it. For example, the above message would be sent on phone as follows: "Number one routine HX Golf W1AW eight Newington Connecticut one eight three zero zulu July one Donald Smith Figures one six four East Sixth Avenue North River City Missouri zero zero seven eight nine Telephone seven three three four nine six eight Break Happy birthday X-ray see you soon X-ray love Break Diana End of Message Over. "End of Message" is followed by "More" if there is another message to follow, "No More" if it is the only or last message. Speak clearly using VOX (or pause frequently on push-to-talk) so that the receiving station can get fills. Spell phonetically all difficult or unusual words — do not spell out common words. Do not use CW abbreviations or Q-signals in phone traffic handling.

## PRECEDENCES

The precedence will follow the message number. For example, on CW 207R or 207 EMERGENCY. On phone, "Two Zero Seven, Routine (or Emergency)."

**EMERGENCY** — Any message having life and death urgency to any person or group of persons, which is transmitted by Amateur Radio in the absence of regular commercial facilities. This includes official messages of welfare agencies during emergencies requesting supplies, materials or instructions vital to relief of stricken populace in emergency areas. During normal times, it will be very rare. On CW, this designation will always be spelled out. When in doubt, do not use it.

**PRIORITY** — Important messages having a specific time limit. Official messages not covered in the Emergency category. Press dispatches and other emergency-related traffic not of the utmost urgency. Notification of death or injury in a disaster area, personal or official. Use the abbreviation P on CW.

**WELFARE** — A message that is either a) an inquiry as to the health and welfare of an individual in the disaster area or b) an advisory or reply from the disaster area that indicates all is well should carry this precedence, which is abbreviated W on CW. These messages are handled after Emergency and Priority traffic but before Routine.

**ROUTINE** — Most traffic normal times will bear this designation. In disaster situations, traffic labeled Routine (R on CW) should be handled last, or not at all when circuits are busy with Emergency, Priority or Welfare traffic.

## Handling Instructions (Optional)

**HXA** — (Followed by number.) Collect landline delivery authorized by addressee within ..... miles. (If no number, authorization is unlimited.)

**HXB** — (Followed by number.) Cancel message if not delivered within ..... hours of filing time; service originating station.

**HXC** — Report date and time of delivery (TOD) to originating station.

**HXD** — Report to originating station the identity of station from which received, plus date and time. Report identity of station to which relayed, plus date and time, or if delivered report date, time and method of delivery.

**HXE** — Delivering station get reply from addressee, originate message back.

**HXF** — (Followed by number.) Hold delivery until ..... (date).

**HXG** — Delivery by mail or landline toll call not required. If toll or other expense involved, cancel message and service originating station.

For further information on traffic handling, consult the *Public Service Communications Manual* or the *ARRL Operating Manual*, both published by ARRL.

FSD-218 (585)

ARRL HQ, 225 Main St., Newington, CT 06111

during an emergency.

After an emergency, tell your EC or net manager of your activities, so a timely report is submitted to ARRL HQ. Each month *QST* chronicles Amateur Radio's emergency communications efforts.

The Amateur Radio Service has been a vital part of emergency communications for more than 50 years, whether it be relaying medical traffic into an earthquake-ravaged village in South America, answering "Mayday" from a ship in the Pacific Ocean, or finding out if a neighbor's relative survived a blizzard in the Midwest.

Why not become a part of it!

## Volunteer Monitoring

Another significant role for the ARRL Field Organization is in volunteer monitoring. The Communications Amendments Act of 1982 (commonly referred to as Public Law 97-259) made it possible for the FCC to formally use volunteer Amateur Radio operators to monitor the ham bands for rules violations. This is a crucial factor in maintaining order and the traditional high standards of the Amateur Radio Service, as governmental belt-tightening no longer provides the FCC's Field Operations Bureau with the necessary resources to monitor the amateur bands to any great extent. Therefore, the FCC created the Amateur Auxiliary to its Field Operations Bureau, implemented by the ARRL Field Organization.

The Amateur Auxiliary addresses both day-to-day maintenance monitoring (conducted by the League's well-established Official Observer program) and amateur-to-amateur interference. Maintenance monitoring is carried out through an enhanced ARRL Official Observer program, while amateur-to-amateur interference is handled by specifically authorized Local Interference Committees. ARRL sections are the focal point for liaison and the primary communications channel between organized amateurs and the FCC's Field Operations Bureau. In effect, the Amateur Auxiliary will be administered through the League's Section Managers. See page 8 of *QST* for a listing of Section Managers.

The FCC has publicly acknowledged that the Amateur Radio Service has traditionally been the most self-regulated and disciplined service over which it has jurisdiction. The Amateur Auxiliary is a direct response to self-regulation and the confidence that is placed in amateurs by the FCC. Such self-regulation increases in importance as the trend of federal deregulation accelerates. The basic message is that amateur problems are for amateurs to solve, by the experts: The Amateur Auxiliary. For more information on volunteer monitoring see Chapter 39.

## W1AW: ARRL HQ. Station

The Maxim Memorial Station, W1AW, is dedicated to serve the amateur fraterni-

reference material and do a little monitoring beforehand, you shouldn't have much of a problem. In fact, the many slow-speed nets that meet on the Novice frequencies are a boon to learning the simple procedures.

Each day, hams enjoy the challenge of these activities. Why not check into a net and check it out!

## What You Should Do

Before an emergency occurs, prepare for it by keeping your station and emergency power supply (if you have one) in

good working order. Participate in the annual nationwide Simulated Emergency Test, contests and Field Day.

Register your station with your local EC. During an emergency, report to the EC at once and follow the EC's directions.

Monitor your local emergency net frequency, but don't transmit unless you are specifically requested to or are certain you can be of assistance.

Copy special WIAW bulletins for latest developments.

Use your receiver more, your transmitter less. Interference can be intense

All W1AW CW code practice, Baudot, CW, AMTOR and ASCII bulletin transmissions are now generated by computer.

The W1AW visitors' operating position is on the left, and the satellite ground station is on the right.

ty. It is adjacent to the ARRL Hq. offices and is operated by the Headquarters Operators Club. Operating hours are 8:30 A.M. to 1 A.M. Monday through Friday and 3:30 P.M. to 1 A.M. Saturday and Sunday. The station is open to visitors at all times it is in operation. If you wish to operate W1AW while visiting, the period between 1 and 4 P.M., Monday through Friday, is available. Be sure to bring a copy of your FCC license with you if you plan to operate.

#### W1AW Code Practice

Code practice is sent on approximately 1.818, 3.58, 7.08, 14.07, 21.08, 28.08, 50.08 and 147.555 MHz. Texts are from recent issues of *QST* and checking references are sent several times during each session. For practice purposes, the order of words in each line of text may be reversed during the 5-15 WPM transmissions. Two code proficiency qualifying runs are sent each month; dates are in the "Contest Corral" section of *QST*. Here is the code practice schedule:

Speeds  
5, 7½, 10, 13, 15 WPM

EST/EDST	PST/PDST
9 A.M. MWF	6 A.M. MWF
7 P.M. MWF	4 P.M. MWF
4 & 10 P.M. TTHSSU	1 & 7 P.M. TTHSSU

Speeds  
35, 30, 25, 20, 15, 13,  
10 WPM

EST/EDST	PST/PDST
9 A.M. TTH	6 A.M. TTH
7 P.M. TTHSSU	4 P.M. TTHSSU
4 & 10 P.M. MWF	1 & 7 P.M. MWF

#### Bulletins

CW bulletins at 18 WPM are sent daily at 5, 8 and 11 P.M. and Monday through Friday at 10 A.M. EST/EDST. Frequencies are the same as those used for code practice.

Baudot radioteletype bulletins, at 60 WPM with 170-Hz shift, are sent daily at 6, 9 and 12 P.M. and Monday through Friday at 11 A.M. EST/EDST. Each Baudot bulletin is followed by a repeat on 110-baud

#### W1AW Special Emergency Bulletin Schedule

Phone on the hour: 1890, 3990, 7290, 14,290, 21,390, 28,590, 50,190, 147,555 kHz.  
RTTY 15 minutes past the hour: 3625, 7095, 14,095, 21,095, 28,095, 147,555 kHz.  
CW on the half hour: 1818, 3580, 7080, 14,070, 21,080, 28,080, 50,080, 147,555 kHz.

ASCII. Frequencies are 3.625, 7.095, 14.095, 21.095, 28.095 and 147.555 MHz. Transmissions on AMTOR Mode B will follow the Baudot/ASCII bulletins when time permits.

Voice bulletins are daily at 9:30 P.M. and 12:30 A.M. EST/EDST on 1.890, 3.990, 7.290, 14.290, 21.390, 28.590, 50.19 and 147.555 MHz.

A complete W1AW schedule is available from ARRL Hq. for an s.a.s.e.

#### General Operation

W1AW is equipped for operation on all bands from 1.8 to 144 MHz, and for teleprinter, and satellite communications as well as for CW, SSB and FM.

# Monitoring and Direction Finding

**R**adio direction finding is almost as old as radio itself. Frequently called RDF, the location of radio transmitters with direction-finding techniques is considered by many to be either an art or a science — or perhaps a bit of both. Although sophisticated and complex equipment pushing the state of the art has been developed for use by governments and commercial enterprises, relatively simple equipment can be built at home to offer the radio amateur an opportunity to RDF.

In many countries of the world, the hunting of hidden transmitters takes on the atmosphere of a sport, as participants wearing jogging togs or track suits dash toward the area where they believe the transmitter is located. The sport is variously known as fox hunting, bunny hunting, ARDF (Amateur Radio direction finding) or simply transmitter hunting. In North America, most hunting of hidden transmitters is conducted from automobiles, although hunts on foot are gaining popularity.

There is a more serious side to RDF, as well. Although not directly related to Amateur Radio, radio navigation is one application of RDF. The locating of downed aircraft is another, and one in which amateurs often lend their skills. Or sometimes a stolen amateur rig will be placed into operation by a person who is not familiar with Amateur Radio, and by being lured into making frequent transmissions, the operator unsuspectingly permits himself to be located by hams using RDF equipment. Jammers of repeaters, traffic nets and other amateur operations can also be located with RDF equipment. Indeed, it has many useful applications.

### Volunteer Monitoring

An important aspect of the Communications Amendments Act of 1982, commonly known as Public Law 97-259, is one that authorized the FCC to formally enlist the use of amateur volunteers for monitoring the airwaves and for rules violations. To

implement volunteer monitoring, the FCC's Field Operations Bureau has created an Amateur Auxiliary, administered by the League's Section Managers.

The Auxiliary is concerned with both maintenance monitoring and amateur-to-amateur interference. Maintenance monitoring is conducted through an enhanced ARRL Official Observer program, while amateur-to-amateur interference is handled by specifically authorized Local Interference Committees. To locate offenders, such committees must rely in a large part on RDF techniques. Thus, RDF becomes a federally sanctioned activity in Amateur Radio.

### DIRECTION-FINDING SYSTEMS

Required for any RDF system are a directive antenna and a device for detecting the radio signal. In Amateur Radio applications the signal detector is usually a receiver; for convenience it will have a meter to indicate signal strength. At very close ranges a simple diode detector and dc microammeter may suffice for the signal detector.

The receiver may be a small portable, a mobile or the regular fixed-station instrument. In government or commercial installations the "receiver" is usually a system of electronics coupled to a cathode-ray tube that indicates azimuth. Antennas used in these systems use electronic beam forming, discussed in a later section. But for amateur use, a standard, unmodified, commercially available receiver works well. Some enterprising amateurs have designed and built their own receivers for RDF work, but their primary goal has usually been portability that is not offered in commercially made equipment. The point is this: If you want to try your hand at RDF, going out to buy a special RDF receiver is *not* one of the considerations.

Antennas for RDF work, on the other hand, are not generally the types used for normal two-way communications. Directivity is a prime requirement, and here the

word directivity takes on a somewhat different meaning than is commonly applied to antennas. Normally we associate directivity with gain, and we think of the ideal antenna pattern as one having a long, thin main lobe. Such a pattern may be of value for coarse measurements in RDF work, but precise bearing measurements are not possible. There is always a spread of a few (or perhaps many) degrees on the "nose" of the lobe where a shift of antenna bearing produces no detectable change in signal strength. In RDF measurements, it is desirable to correlate an exact bearing or compass direction with the position of the antenna. To do this accurately, an antenna exhibiting a null in its pattern is used. A null can be very sharp in directivity, to within a half degree or less.

### Loop Antennas

A simple antenna for RDF work is a small loop tuned to resonance with a capacitor. Several factors must be considered in the design of an RDF loop. The loop must be small compared with the wavelength. In a single-turn loop, the conductor should be less than 0.08 wavelength long. For 28 MHz, this represents a length of less than 34 inches (diameter of approximately 10 inches). Maximum response from the loop antenna is in the plane of the loop, with nulls exhibited at right angles to that plane.

To obtain the most accurate bearings, the loop must be balanced electrostatically with respect to ground. Otherwise, the loop will exhibit two modes of operation. One is the mode of a true loop, while the other is that of an essentially non-directional vertical antenna of small dimensions ("antenna effect"). The voltages introduced by the two modes are not in phase and may add or subtract, depending on the direction from which the wave is coming.

The theoretical true loop pattern is illustrated in Fig. 1A. When properly balanced, the loop exhibits two nulls that

are  $180^\circ$  apart. Thus, a single null reading with a small loop antenna will not indicate the exact direction toward the transmitter — only the line along which the transmitter lies. Ways to overcome this ambiguity are discussed in later sections.

When the antenna effect is appreciable and the loop is tuned to resonance, the loop may exhibit little directivity, as shown in Fig. 1B. However, by detuning the loop to shift the phasing, a pattern similar to C may be obtained. Although this pattern is not symmetrical, it does exhibit a null. The null, however, may not be as sharp as that obtained with a loop that is well balanced, and may not be at exact right angles to the plane of the loop.

By suitable detuning, the unidirectional pattern of Fig. 1D may be approached. This adjustment is sometimes used in RDF work to obtain a unidirectional bearing, although there is no complete null in the pattern. In most cases, however, the loop is adjusted for the best null.

An electrostatic balance can be obtained by shielding the loop, as shown in Fig. 2. The shield is represented by the broken lines in the drawing, and eliminates the antenna effect. The response of a well-constructed shielded loop is quite close to the ideal pattern of Fig. 1A.

For the low-frequency amateur bands, single-turn loops of convenient physical size for portability are generally unsatisfactory for RDF work. Therefore, multi-turn loops are generally used instead. Such a loop is shown in Fig. 3. This loop may also be shielded, and if the total conductor length remains below 0.08 wavelength, the directional pattern is that of Fig. 1A.

### Ferrite Rod Antennas

The development of magnetic core materials has led to the use of loop antennas with such cores. These antennas consist essentially of many turns of wire around a ferrite rod. They are known as loopstick antennas and also as ferrite-rod antennas. Probably the best-known example of this type of antenna is that used in small portable AM broadcast receivers. The advantage of ferrite-rod antennas is their reduced size. For portable work, loopsticks are used almost exclusively for frequencies below 150 MHz.

As implied in the earlier discussion of shielded loops in this chapter, the true loop antenna responds to the magnetic field of the radio wave, and not to the electrical field. The voltage delivered by the loop is proportional to the amount of magnetic flux passing through the coil, and to the number of turns in the coil. The action is much the same as in the secondary winding of a transformer. For a given size of loop, the output voltage can be increased by increasing the flux density, and this is done with a ferrite core of high permeability. A  $\frac{1}{2}$ -inch-diameter, 7-inch rod of Q2 ferrite ( $\mu_r = 125$ ) is suitable for a loop core from

### The Practical Side of Fox Hunting

Recently a co-worker, Ed Dabrowski, W8NLO and I went on a peculiar type of fox hunt. Ed and I are engineers for a Chicago TV station. About two weeks prior to the fox hunt I began noticing a herringbone pattern on TV Channel 2 on my home TV sets. The pattern was relatively weak with no audible modulation and a slight variance in frequency. The herringbone pattern was sometimes on for most of the day and at other times for just a short while. It was enough to make watching Channel 2 frustrating. I asked my immediate neighbors if they were having the same trouble, and they were. I then drove around the neighborhood to see if any new CB or other antennas had been put up recently. Finding none, I checked some of the nearby industries and a nursing home to see if they were using any induction or dielectric heaters, or diathermy. Again I drew a blank.

Then, to add to my frustrations, I started getting phone calls blaming me for the disturbance on Channel 2. Five antennas on my tower and three more on my roof make me a prime target for such blame. I checked all of my receivers to see if I could locate a spur that was causing the problem. Next I connected my 2-meter beam to a TV set and made a sweep of the area. The signal seemed to be coming from within my subdivision.

The FCC was contacted and I explained to one of the field engineers just what was happening and what I had done so far. He suggested looking for a TV booster amplifier that had gone bad. He indicated that they sometimes go into self-oscillation and radiate through the TV antenna.

On that advice I called out the reserves. Ed helped me wire up my 5-inch portable so we would be able to use it in the car. We took a bearing on the signal and plotted it on a map of the subdivision. It was dark as we drove around trying to locate the source of the signal. We pinned it down to a few houses, began knocking on doors and explained the situation. We asked the residents if they had recently bought any new electronic devices or if they had a TV antenna booster amplifier. Ed and I also asked the residents to turn off the main power to their houses to see if the herringbone interference would be eliminated. People were very cooperative as we announced ourselves as TV engineers and Amateur Radio operators. One of the homeowners said, "Oh yeah, I know where the trouble is coming from. It's that guy about two blocks west of here with the big tower in his backyard." He was quite embarrassed when I told him that I was the guy he was referring to and that I was trying to locate the source of the signal.

We checked all of the houses in the suspect area, except one where the people were not at home. We were about to pack up when the owners came home. We showed them the portable TV in the car and asked them to turn off their power. When the power was turned off the interference went away. *We had found it!* The residents indeed had a TV antenna booster amplifier in the attic. It has since been disconnected or repaired, and TV Channel 2 is clear and sharp with no herringbone. Our local community newsletter printed a nice word for us and I got off the hook with the neighbors who suspected me of causing the problem.

the broadcast band through 10 MHz. For increased output, the turns may be wound on two rods that are taped together, as shown in Fig. 4. Loopstick antennas for construction are described later in this chapter.

Maximum response of the loopstick antenna is broadside to the axis of the rod as shown in Fig. 5, whereas maximum response of the small loop is in the plane of the loop. Otherwise the performances of the ferrite-rod antenna and of the ordinary loop are similar. The loopstick may also be shielded to eliminate the antenna effect, such as with a U-shaped or C-shaped channel of aluminum or other form of "trough." The length of the shield should equal or slightly exceed the length of the rod.

### Sensing Antennas

Because there are two nulls that are  $180^\circ$  apart in the directional pattern of a loop or a loopstick, an ambiguity exists as to which one indicates the true direction of the station being tracked. For example, assume you take a bearing measurement and the result indicates the transmitter is somewhere on a line running approximately east and west from your position. With this single reading, you have no way of know-

Fig. 1 — Small-loop field patterns with varying amounts of antenna effect — the undesired response of the loop acting merely as a mass of metal connected to the receiver antenna terminals. The heavy lines show the plane of the loop.

ing for sure if the transmitter is east of you or west of you.

If there is more than one receiving station taking bearings on a single transmitter, or if a single receiving station takes bearings from more than one position on the transmitter, the ambiguity may be worked out by a method called triangulation. (Further detail on triangulation is

Fig. 2 — Shielded loop for direction finding. The ends of the shielding turn are not connected, to prevent shielding the loop from magnetic fields. The shield is effective against electric fields.

Fig. 3 — Small loop consisting of several turns of wire. The total conductor length is very much less than a wavelength. Maximum response is in the plane of the loop.

Fig. 4 — A ferrite-rod or loopstick antenna. Turns of wire may be wound on a single rod or, to increase the output from the loop, the core may be two rods taped together, as shown here. The type of core material must be selected for the intended frequency range of the loop. To avoid bulky windings, fine wire such as no. 28 or no. 30 is often used, with larger wire for the leads.

given in a later section.) However, it is sometimes desirable to have a pattern with only one null, so there is no question about

whether the transmitter in the above example would be east or west from your position.

A loop or loopstick antenna may be made to have a single null if a second antenna element is added. The element is called a sensing antenna, because it gives an added sense of direction to the loop pattern. The second element must be omnidirectional, such as a short vertical. When the signals from the loop and the vertical element are combined with a  $90^\circ$  phase shift between the two, a cardioid pattern results. The development of the pattern is shown in Fig. 6A.

Fig. 6B shows a circuit for adding a sensing antenna to a loop or loopstick. R1 is an internal adjustment and is used to set the level of the signal from the sensing antenna. For the best null in the composite pattern, the signals from the loop and the sensing antenna must be of equal amplitude, so R1 is adjusted experimentally during setup. In practice, the null of the cardioid is not as sharp as that of the loop, so the usual measurement procedure is to first use the loop alone to obtain a precise bearing reading, and then to add the sensing antenna and take another reading to resolve the ambiguity. (The null of the cardioid is  $90^\circ$  away from the nulls of the loop.) For this reason, provisions are usually made for switching the sensing element in and out of operation.

#### Phased Arrays

Phased arrays are also used in amateur RDF work. Two general classifications of phased arrays are end-fire and broadside configurations. Depending on the spacing and phasing of the elements, end-fire patterns may exhibit a null off one end of the axis of the two or more elements. At the same time, the response is maximum off the other end of the axis, in the opposite direction from the null. A familiar arrangement is two elements spaced  $\frac{1}{4}$  wavelength apart and fed  $90^\circ$  out of phase. The resultant pattern is a cardioid, with the null in the direction of the leading element. Other arrangements of spacing and phasing for an end-fire array are also suitable for RDF work. One of the best known is the Adcock array, discussed in the next section.

Broadside arrays are inherently bidirectional, which means there are always at least two nulls in the pattern. Ambiguity therefore exists in the true direction of the transmitter, but depending on the application, this may be no handicap. Broadside arrays are seldom used for amateur RDF applications.

#### Adcock Arrays

One of the most popular types of end-fire phased arrays is the Adcock. This system was invented by F. Adcock and patented in 1919. The array consists of two vertical elements fed  $180^\circ$  apart, and

mounted so the system may be rotated. Element spacing is not critical, and may be in the range from  $\frac{1}{10}$  to  $\frac{3}{4}$  wavelength. The two elements must be of identical lengths, but need not be self-resonant. Elements that are shorter than resonant are commonly used. Because neither the element spacing nor the length is critical in terms of wavelengths, an Adcock array may be operated over more than one amateur band.

The radiation pattern of the Adcock is shown in Fig. 7A. The nulls are in directions broadside to the axis of array, and become sharper with greater element spacings. However, with an element spacing greater than  $\frac{1}{4}$  wavelength, the pattern begins to take on additional nulls in the directions off the ends of the array axis. At a spacing of 1 wavelength the pattern is that of Fig. 7B, and the array is unsuitable for RDF applications.

Short vertical monopoles are often used in what is sometimes called the U-Adcock, so named because the elements with their feeders take on the shape of the letter U. In this arrangement the elements are worked against the earth as a ground or counterpoise. If the array is used only for reception, earth losses are of no great consequence. Short, elevated vertical dipoles are also used in what is sometimes called the H-Adcock. The Adcock array is often used at HF for skywave RDF work. In this application, it is not considered a portable system.

The Adcock array, with two nulls in its pattern, has the same ambiguity as the loop and the loopstick. Adding a sensing element to the Adcock array has not met with great success. Difficulties arise from mutual coupling between the array elements and the sensing element, among other things. Because Adcock arrays are

Fig. 5 — Field pattern for a ferrite rod antenna. The dark bar represents the rod on which the loop turns are wound.

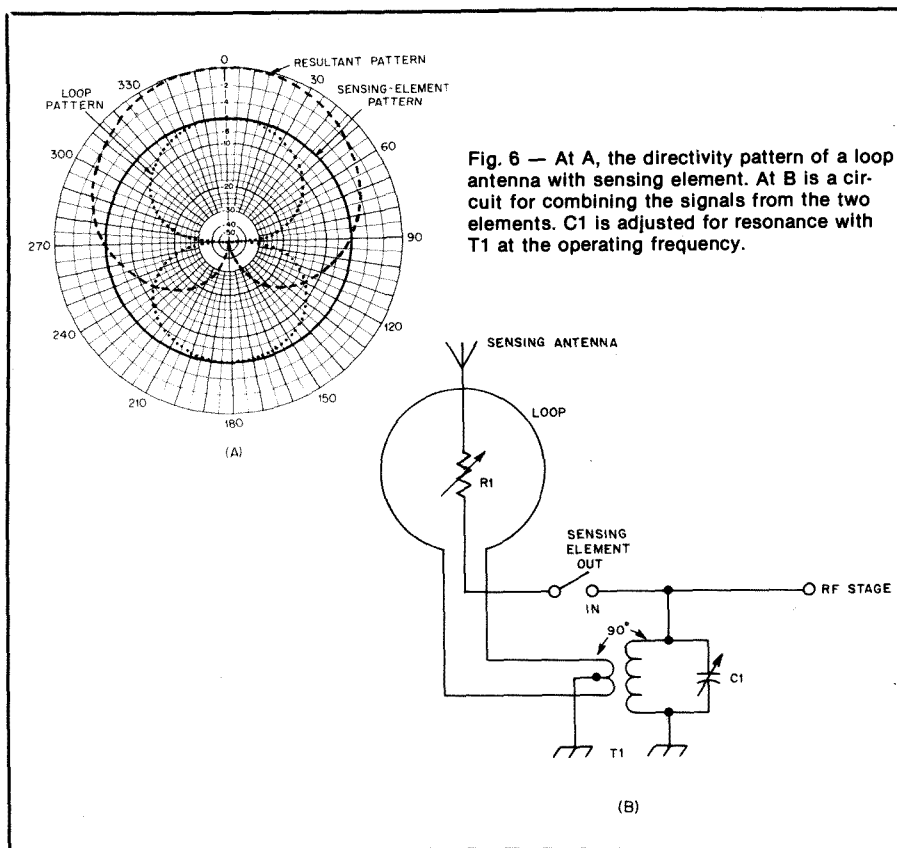

Fig. 6 — At A, the directivity pattern of a loop antenna with sensing element. At B is a circuit for combining the signals from the two elements. C1 is adjusted for resonance with T1 at the operating frequency.

Fig. 8 — An early type of goniometer that is still used today in some RDF applications. This device is a special type of RF transformer that permits a movable coil in the center (not shown here) to be rotated and determine directions even though the elements connected at A and B are stationary.

Fig. 9 — This diagram illustrates one technique used in electronic beam forming. By delaying the signal from element A by an amount equal to the propagation delay, the two signals may be summed precisely in phase, even though the signal is not in the broadside direction. Because this time delay is identical for all frequencies, the system is not frequency sensitive.

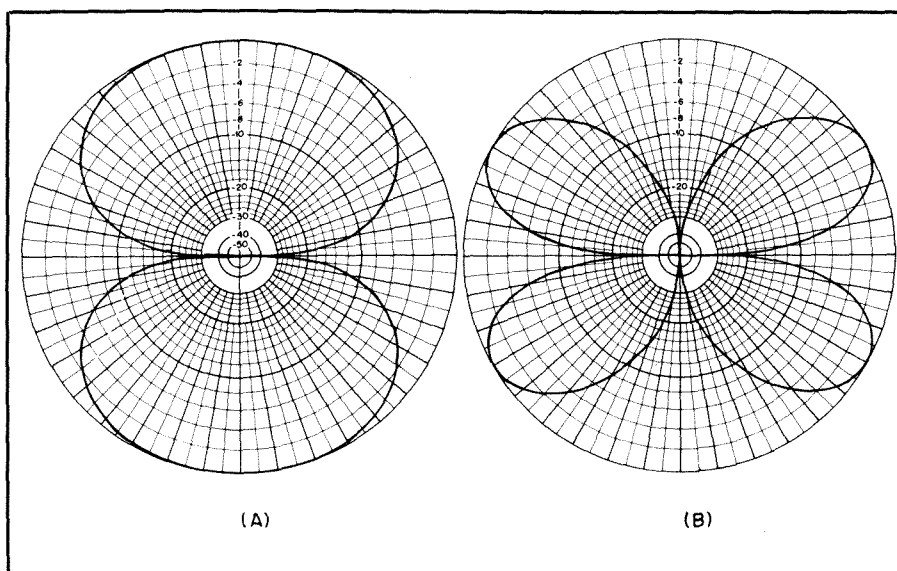

Fig. 7 — At A, the pattern of the Adcock array with an element spacing of  $\frac{1}{2}$  wavelength. In these plots the elements are aligned with the vertical axis. As the element spacing is increased beyond  $\frac{1}{4}$  wavelength, additional nulls develop off the ends of the array, and at a spacing of 1 wavelength the pattern at B exists. This pattern is unsuitable for RDF work.

used primarily for fixed-station applications, the ambiguity presents no serious problem. The fixed station with an Adcock is usually one of a group of stations in an RDF network.

#### Loops vs. Phased Arrays

Although loops can be made smaller than suitable phased arrays for the same frequency of operation, the phased arrays

are preferred by some for a variety of reasons. In general, sharper nulls can be obtained with phased arrays, but this is also a function of the care used in constructing and feeding the individual antennas, as well as of the size of the phased array in terms of wavelengths. The primary constructional consideration is the shielding and balancing of the feed line against unwanted signal pickup, and the

balancing of the antenna for a symmetrical pattern.

Loops are not as useful for skywave RDF work because of random polarization of the received signal. Phased arrays are somewhat less sensitive to propagation effects, probably because they are larger for the same frequency of operation and therefore offer some space diversity. In general, loops and loopsticks are used for mobile and portable operation, while phased arrays are used for fixed-station operation. However, phased arrays are used successfully above 144 MHz for portable and mobile RDF work. Practical examples of both types of antennas are presented later in this chapter.

#### The Goniometer

Most fixed RDF stations for government and commercial work use antenna arrays of stationary elements, rather than mechanically rotatable arrays. This has been true since the earliest days of radio. The device used in those early days to permit finding directions without moving the elements is called a radiogoniometer, or simply a goniometer. Various types of goniometers are still used today in many

installations, and offer the amateur many possibilities.

The early style of goniometer is a special form of RF transformer, as shown in Fig. 8. It consists of two fixed coils mounted at right angles to one another. Inside the fixed coils is a movable coil, not shown in Fig. 8 to avoid cluttering the diagram. The pairs of connections marked A and B are connected respectively to two elements in an array, and the output to the detector or receiver is taken from the movable coil. As the inner coil is rotated, its coupling to one fixed coil increases while that to the other decreases. Both the amplitude and the phase of the signal coupled into the pickup winding are altered with rotation in a way that corresponds to actually rotating the array itself. Therefore, the rotation of the inner coil can be calibrated in degrees to correspond to bearing angles from the station location.

In the early days of radio, the type of goniometer just described saw frequent use with fixed Adcock arrays. A refinement of that system employed four Adcock elements, two arrays at right angles to each other. With a goniometer arrangement, RDF measurements could be taken in all compass directions, as opposed to none off the ends of a two-element fixed array. However, resolution of the four-element system was not as good as with a single pair of rotatable elements. To overcome this difficulty, a few systems of eight elements were installed.

Various other types of goniometers have been developed over the years, such as commutator switching to various elements in the array. A later development is the diode switching of capacitors to provide a commutator effect. As mechanical action has gradually been replaced with electronics to "rotate" stationary elements, the word goniometer is used less frequently these days. However, it still appears in many engineering reference texts. The more complex electronic systems of today are often called beam-forming networks.

#### Electronic Antenna Rotation

With an array of many fixed elements, beam rotation can be performed electronically by sampling and combining signals from various individual elements in the array. Contingent on the total

number of elements in the system and their physical arrangement, almost any desired antenna pattern can be formed by summing the sampled signals in appropriate amplitude and phase relationships. Delay networks are used for some of the elements before the summation is performed. In addition, attenuators may be used for some elements to develop patterns such as from an array with binomial current distribution.

One system using these techniques is the Wullenweber antenna, used primarily in government and military installations. The Wullenweber consists of a very large number of elements arranged in a circle, usually outside of (or in front of) a circular reflecting screen. Depending on the installation, the circle may be anywhere from a few hundred feet to more than a quarter of a mile in diameter. Although the Wullenweber is not one that would be constructed by an amateur, some of the techniques it uses may certainly be applied to Amateur Radio.

For the moment, consider just two elements of a Wullenweber antenna, shown as A and B in Fig. 9. Also shown is the wavefront of a radio signal arriving from a distant transmitter. As drawn, the wavefront strikes element A first, and must travel somewhat farther before it strikes element B. There is a finite delay before the wavefront reaches element B.

The propagation delay may be measured by delaying the signal received at element A before summing it with that from element B. If the two signals are combined directly, the amplitude of the resultant signal will be maximum when the delay for element A exactly equals the propagation delay. This results in an in-phase condition at the summation point. Or if one of the signals is inverted and the two are summed, a null will exist when the element-A delay equals the propagation delay; the signals will combine in a 180° out-of-phase relationship. Either way, once the time delay is known, it may be converted to distance. Then the direction from which the wave is arriving may be determined by trigonometry.

By altering the delay in small increments, the peak of the antenna lobe (or the null) can be steered in azimuth. This is true without regard to the frequency of the incoming wave. Thus, the system is not fre-

quency sensitive, other than for the frequency range that may be covered satisfactorily by the array elements themselves. Delay lines used in such systems can be lumped-constant networks if the system is used only for receiving. Rolls of coaxial cable of various lengths are used in installations for transmitting. In this case, the lines are considered for the time delay they provide, rather than as simple phasing lines. The difference is that a phasing line is ordinarily designed for a single frequency (or for an amateur band), while a delay line offers essentially the same delay at all frequencies.

By combining signals from other Wullenweber elements appropriately, the broad beamwidth of the pattern from the two elements can be narrowed, and unwanted sidelobes can be suppressed. Then, by electronically switching the delays and attenuations to the various elements, the beam so formed can be rotated around the compass. The package of electronics designed to do this, including delay lines and electronically switched attenuators, is the beam-forming network. However, the Wullenweber system is not restricted to forming a single beam. With an isolation amplifier provided for each element of the array, several beam-forming networks can be operated independently. Imagine having an antenna system that offers a dipole pattern, a rhombic pattern and a Yagi beam pattern, all simultaneously and without frequency sensitivity. One or more may be rotating while another is held in a particular direction. The Wullenweber was designed to fulfill this type of requirement.

One feature of the Wullenweber antenna is that it can operate at 360° around the compass. In many government installations, there is no need for such coverage, as the areas of interest lie in a single azimuth sector. In such cases an in-line array of elements with a backscreen or curtain reflector may be installed broadside to the center of the sector. By using the same techniques as the Wullenweber, the beams formed from this array may be slewed left and right across the sector. The maximum sector width available will depend on the installation, but beyond 70 to 80° the patterns begin to deteriorate to the point that they are unsatisfactory for precise RDF work.

# Direction Finding Techniques

Locating a transmitter with RDF techniques is a skill that is acquired only with practice. Familiarity with the antenna being used and especially with its limitations are probably the most important criteria. Of course, knowing the measuring equipment is also a requirement. But in addition to this, one must know how radio signals behave at different frequencies and in different kinds of terrain. Here is where experience becomes the best teacher, although reading about the experiences of others and talking with others who are active in RDF also helps.

## GROUND-WAVE RDF

Most amateur RDF activity is conducted with ground-wave signals, where the transmitter is seldom more than a dozen or so miles away. Even if the position of a transmitter has been localized with sky-wave measurements, it is usually not possible to determine the precise transmitter location without taking some ground-wave readings. The considerations for these measurements are discussed in this section. Some of these considerations also apply to sky-wave measurements, but a later section discusses the peculiarities of sky-wave RDF work.

Before setting out to locate a signal source, it is a good idea to note some general information about the signal itself. Is its frequency constant, or does it drift? Drifting means you may have to retune the receiver often during the hunt. Do transmissions occur at rather regular intervals, or are they sporadic? Are transmissions very short in duration, modest in length, or is there a continuous carrier? The most difficult sources to locate are those which transmit at irregular intervals and are on the air for very brief periods, such as a few seconds. Finding these transmitters becomes a real challenge and requires extreme patience. It also requires quick action when the transmitter is on the air, to obtain a null reading in those few seconds. Once you've determined the general signal characteristics, you can begin the search.

Best accuracy in determining a bearing to a signal source is obtained when the propagation path is over homogeneous terrain, and when only the vertically polarized component of the ground wave is present. If a boundary exists such as between land and water, the different conductivities of the two mediums under the ground wave cause bending (refraction) of the wave front. In addition, reflection of RF energy from vertical objects such as mountains or buildings can add to the direct wave and cause RDF errors.

The effects of refraction and reflection are shown in Fig. 10. At A, the signal is actually arriving from a different bearing than the true direction to the transmitter.

Fig. 10 — RDF errors caused by refraction (A) and reflection (B). At A a false reading is obtained because the signal actually arrives from a direction that is different from that to the source. At B a direct signal from the source combines with a reflected signal from the mountain ridge. The two are averaged at the antenna, giving a false bearing to a point somewhere between the two apparent sources.

This happens because the wave is refracted at the shoreline. Even the most sophisticated of measuring equipment will not indicate the true bearing in this situation, as the equipment can only show the direction from which the signal is arriving. Knowing how radio signals behave at different frequencies and in different kinds of terrain is important in this situation. If the measuring equipment is portable, the experienced RDF enthusiast will probably move to the shoreline to take a measurement with less chance of error. Even so, depending on the direction to the source compared to the direction of the shoreline, a precise reading may still be impossible to obtain.

In Fig. 10B there are two apparent sources for the incoming signal — a direct wave from the source itself, and another wave that is reflected from the mountain ridge. In this case the two waves add at the antenna of the RDF equipment. Without care being used in performing the measurement, the uninitiated observer would obtain a false bearing in a direction somewhere between the directions to the two sources. The experienced RDF enthusiast might notice that the null reading in this situation is not as sharp as it usually is, or perhaps not as deep. But these indications would be subtle, and easy to overlook. Here is where knowing the antenna and the equipment becomes very helpful.

Water towers, tall radio towers and similar objects can also lead to false bearings. The effects of these objects become significant when they are large in terms of a wavelength. In fact, if the direct path to the transmitter is masked

by intervening terrain or other radio "clutter," it is possible that a far stronger signal may be received by reflection than from the true direction to the source. Such towers atop hills are prime sources of strong "pinpoint" reflections. Triangulation may even "confirm" that the transmitter is at that high elevation, unless a reading is taken from in the clear, where the true radio path is unmasked by the clutter.

Local objects also tend to distort the field, such as buildings of concrete and steel construction, power lines and the like. It is important that the RDF antenna be in the clear, well away from such surrounding objects. Trees with foliage may also create an adverse effect, especially at VHF and above. If it is not possible to avoid such objects, the best procedure is to take readings at several different positions, and to average the readings for the result.

## Triangulation

If two RDF bearing measurements are taken from locations that are separated by a significant distance, the bearing lines may be drawn from those positions as represented on a map. The point where the two lines cross (assuming the two bearings are not the same nor are 180° apart) will indicate a "fix," or the approximate position of the transmitter.

The word "approximate" is used here because there is always some degree of uncertainty in the readings obtained from the measurement. This uncertainty arises from equipment limitations (antenna null width, for example). Propagation effects

Fig. 11 — Bearing sectors from three RDF positions drawn on a map. This method is known as triangulation. Note here that sensing antennas are not required at any of the DF sites; antennas with two null indications 180° apart are quite acceptable.

may increase the degree of uncertainty. In order to obtain a more precise fix, a bearing measurement from yet a third position is helpful. When the positions and bearing lines for all three measurements are placed on a map, the three lines seldom intersect at a single point. Instead, they form a small triangle on the map. The unknown source is presumed to be located inside the triangle. Thus, the name triangulation.

In order to best indicate the probable area of the transmitter location on the map, the bearings from each position should be drawn as a narrow sector instead of as a single line. The sector width should represent the amount of uncertainty. A portion of a map marked in this manner is shown in Fig. 11. Here it becomes evident graphically how the measurement from DF Site 3 has narrowed down the probable area of the transmitter position. The small black section indicates where the transmitter is likely to be found, a significantly smaller quadrangle than that of the sectors from DF Sites 1 and 2 alone.

Several types of maps are suitable for triangulation. Ordinary road maps, however, usually lack sufficient detail, and are not generally satisfactory. Contour maps of the area like that shown in Fig. 11 are preferred for open country. Aeronautical charts are also suitable. City maps and street maps are usually acceptable. Your local city or county engineer can help you find a source for suitable maps, perhaps even through his office.

#### Closing in on the Fix

In the final phases of locating an

unknown source, portable RDF equipment is used to pinpoint the exact location. As the equipment is brought near the transmitter, signals become very strong. Overloading of the front-end circuits of the receiver may lead to confusing and inconsistent readings. One way to combat this problem is to insert an attenuator in the transmission line from the antenna to the receiver. Attenuators are discussed in another chapter of this book.

Even with an attenuator in the line, in the presence of a strong electromagnetic field there may be some energy coupled directly into the receiver circuitry. This effect is noted as an apparent nondirectional characteristic of the antenna. In other words, the received signal strength changes only slightly or perhaps not at all as the RDF antenna is rotated in azimuth. The only cure for this effect is to shield the receiving equipment. Something as simple as placing the receiver in a bread pan or cake pan covered with a piece of copper or aluminum screening, securely fastened at several points, may provide sufficient shielding to eliminate this problem. Of course more elaborate precautions may also be taken.

An alternative to protecting the receiver from overload is to switch to a simple diode detector as you are closing in on the fix. The detector should have a sensitive meter indicator with some kind of sensitivity control, and may be made tuneable in frequency, if desired. It might even include a meter-amplifier circuit to increase its sensitivity. It should, however, be constructed inside a metal enclosure

that affords shielding, to avoid unwanted signal pickup in the environment of a strong RF field.

Depending on the nature of the area surrounding the fix, the transmitter may be easy or difficult to locate physically. If the emission is a spurious output from a communications transmitter, a transmitting antenna will probably stand out. On the other hand, a hidden transmitter that is jamming a repeater may be very difficult to find. Sometimes such transmitters are buried in the ground, and the antenna may be a thin wire concealed in the bushes. It may not be spotted by an observer standing right next to it. Sharp eyes and some astute observations are needed here.

#### A Test or Target Transmitter

Some situations may arise where repeated inconsistent RDF readings simply won't yield a reliable fix. This can happen in mountainous or hilly terrain, or in a canyon, where many signal reflections occur. It also happens in the "concrete jungle" of a metropolitan area where canyons are formed by tall buildings. (In this case it may be advantageous to take a reading from atop one of those buildings.)

A simple aid to locating the source of such a signal is to use a test or target transmitter. This is a second transmitter that is temporarily placed in the general area where the unknown source is thought to be located, and operated on a slightly different frequency. RDF readings from the unknown source may then be compared with readings from the target transmitter to gain a better idea of the unknown location. The target transmitter may even be moved about until the readings coincide, to obtain a reliable fix. Successfully tracking down an unknown transmitter involves detective work — examining all the clues, weighing the evidence and using one's best judgment. For many amateurs, RDF presents an interesting challenge.

#### SKY-WAVE RDF

Many factors make it difficult to obtain accuracy in sky-wave RDF work. In the previous section, mention was made that the vertical component of the signal is used in taking ground-wave measurements. Because of Faraday rotation during propagation, sky-wave signals are received with random polarization — sometimes the vertical component is strongest, and at other times the horizontal. This necessitates somewhat different techniques for sky-wave work, because the vertical component of the signal should still be the one used for bearing measurements. During periods when the vertical component is weak, the signal will appear to fade. At these times, determining an accurate signal null becomes difficult or impossible.

One important thing to keep in mind with sky-wave measurements is the degree of uncertainty. Accuracy to within 1 or 2°

is the exception rather than the rule. Errors of as much as 3 to 5° are common. An error of 3° at a thousand miles represents a distance of 52 miles. Even with every precaution taken in measurements, don't expect to pinpoint a location to more than a county, a corner of a state or a large metropolitan area. What you *can* expect is to determine where an RDF group should begin making a local search.

### Great-Circle Radio Paths

It is generally assumed that a sky-wave signal follows a great-circle path in its travel from a transmitter to a receiver. This is not always the case, however. For example, if the signal is refracted in a tilted layer of the ionosphere, it could arrive from a direction that is several degrees away from the true great-circle bearing. Weather fronts and other meteorological conditions may also result in false readings. Some scientists believe that the earth's magnetic field causes a departure of wave travel from the great-circle path, and propagation conditions during geomagnetic disturbances are known to have this effect.

Another cause of signals arriving off the great-circle path is termed sidescatter. It is possible that, at a given time, the ionosphere does not support great-circle propagation of the signal from the transmitter to the receiver because the frequency is above the MUF for that path. However, at the same time, propagation may be supported from both ends of the path to some mutually accessible point off the great-circle path.

The signal from the source may propagate to that point on the earth's surface and hop in a sideways direction to continue to the receiver. For example, signals from Central Europe have been known to propagate to New England by hopping from an area in the Atlantic Ocean off the northwest coast of Africa, whereas the great-circle path puts the reflection point in the North Atlantic, off the southern coast of Greenland. Readings in error by as much as 50° or more may result from this type of propagation.

Indeed, many factors do combine to make it difficult to obtain accurate sky-wave RDF measurements. The effect may be that the source of the signal seems to wander somewhat over a few minutes of time, or it may be weak and fluttery. At other times, however, there may be no tell-tale signs to indicate that the readings are suspect.

### Antennas for Sky-Wave RDF

Loop antennas and loopsticks are generally unsatisfactory for sky-wave RDF because of not only the random polarization shift, but also because the vertical wave angle from which the signal arrives may not be constant. The Adcock or other type of phased vertical array is used most often. Such arrays offer some degree of space diversity over small loops, and

therefore are less subject to fading effects. Greatest accuracy for sky-wave signals is obtained when the vertical angle of arrival is small.

At high arrival angles, even the Adcock array becomes less reliable because its response to high-angle signals falls off. (It will not respond at all to a signal arriving from directly overhead.) Some experimenters have attempted to overcome this difficulty by tilting the array, but little improvement in reliability seems to result. A tilted loop sometimes yields results equivalent to those of a vertical Adcock array for high-angle signals. Signals from high angles often seem to arrive not from a single point, but from a small area in space. This phenomenon is probably associated with scattering of the signal in the ionosphere.

### Sky-Wave Triangulation

Triangulation mapping with sky-wave signals is a bit more complex than with ground waves because the paths are great-circle routes. Commonly available world maps are difficult to work with, as the triangulation lines must be curved lines, rather than straight. Depending on the method used to create the map, one showing a country or similar large area may be suitable.

Many U.S. highway maps are usable for triangulation work. Most are some form of conical projection, such as the Lambert conformal conic system. The method of developing such a map is shown in Fig. 12. A cone is made to coincide with the earth's surface along two parallels of latitude, and the axis of the cone coincides with that of the earth. The two latitude lines are called standard parallels, and are chosen for the area to be covered for minimum distortion over the entire projection. The standard parallels are located inside the limits of the projection, as shown. This system of coordinates maintains the accuracy of angular representation, but the distance scale is not constant over the entire projection.

A type of map that can be pressed into service for worldwide areas is an azimuthal-equidistant projection, as shown in Fig. 13. This particular map is prepared for Wichita, Kansas, but they may be obtained for any location. Such maps are available for a nominal fee from Bill Johnston, N5KR, 1808 Pomona Dr., Las Cruces, NM 88001. His maps are custom prepared by computer for a specific location.

With an azimuthal-equidistant map, true bearings for great-circle paths are shown as straight lines from the center to all points on the earth. Maps for three or more different RDF sites may be compared to gain an idea of the general geographic area for an unknown source.

A special type of map has been developed that is well suited for sky-wave triangulation. This map is known as a gnomonic projection, one on which *all* great-circle paths are represented by

Fig. 12 — The method of obtaining a Lambert conformal conic projection. To make the average distance errors as small as possible, the two standard parallels are chosen for the area to be mapped. Accuracy of angular representations is maintained.

straight lines. To understand how this is possible, see Fig. 14. The drawing shows a transparent sphere with latitude and longitude lines. A small lamp is positioned at the exact center of the sphere and illuminated.

If a large flat card or sheet of paper is touched against the globe at some point as shown in Fig. 14, the surface features will be projected as shadows on that flat surface. This is the gnomonic projection. All meridians and any lines representing great-circle paths will appear as straight lines on the projection. This happens because the lamp is in the plane of each of the great circles, and cannot therefore throw a curved shadow.

Unfortunately, gnomonic charts are not readily available. They are prepared especially for government agencies and military use. Such a projection can be prepared at home if one wants to take the trouble. The work is tedious. Instructions for making a gnomonic projection are given in pages 749 through 758 of R. Keene (see the bibliography at the end of this chapter).

### RDF SYSTEM CALIBRATION AND USE

Once an RDF system is initially assembled, it should be "calibrated" or checked out before actually being put into use. Of primary concern is the balance or symmetry of the antenna pattern. A lopsided figure-8 pattern with a loop, for example, is undesirable; the nulls are not 180° apart nor are they at exact right angles to the plane of the loop. If this fact was not known in actual RDF work, measurement accuracy would suffer.

Initial checkout can be performed with a low-powered transmitter at a distance of

a few hundred feet. It should be within visual range and must be operating into a vertical antenna. (A quarter-wave vertical or a loaded whip is quite suitable.) The site must be reasonably clear of obstructions, especially steel and concrete or brick buildings, large metal objects, nearby power lines, and so on. If the system operates above 30 MHz, trees and large bushes should also be avoided. An open field makes an excellent site.

The procedure is to "find" the transmitter with the RDF equipment as if its position were not known, and compare the RDF null indication with the visual path to the transmitter. For antennas having more than one null, each null should be checked.

If imbalance is found in the antenna system, there are two options available. One is to correct the imbalance. Toward this end, pay particular attention to the feed line. Using a coaxial feeder for a balanced antenna invites a nonsymmetrical pattern, unless an effective balun is used. A balun is not necessary if the loop is shielded, but a nonsymmetrical pattern can result with misplacement of the break in the shield itself. The builder may also find that the presence of a sensing antenna upsets the balance slightly. Experimenting with its position with respect to the main antenna may lead to correcting the error. You will also note that the position of the null shifts by  $90^\circ$  as the sensing element is switched in and out, and the null is not as deep. This is of little concern, however, as the purpose of the sensing antenna is only to resolve ambiguities. The sensing element should be switched out when accuracy is desired.

The second option is to accept the imbalance of the antenna and use some kind of indicator to show the true directions of the nulls. Small pointers, painted marks on the mast or an optical sighting system might be used. Sometimes the end result of the calibration procedure will be a compromise between these two options, as a perfect electrical balance may be difficult or impossible to attain.

The discussion above is oriented toward calibrating portable RDF systems. The same general suggestions apply if the RDF array is fixed, such as an Adcock. However, it won't be possible to move it to an open field. Instead, the array is calibrated in its intended operating position through the use of a portable or mobile transmitter. Because of nearby obstructions or reflecting objects, the null in the pattern may not appear to indicate the precise direction of the transmitter. Do not confuse this with imbalance in the RDF array. Check for imbalance by rotating the array  $180^\circ$  and comparing readings.

Once the balance is satisfactory, you should make a table of bearing errors noted in different compass directions. These error values should be applied as corrections when actual measurements are made. The

\*Amidon Associates, 12033 Otsego St., North Hollywood, CA 91607

mobile or portable transmitter should be at a distance of 2 or 3 miles for these measurements, and should be in as clear an area as possible during transmissions. The idea is to avoid conduction of the signal along power lines and other overhead wiring from the transmitter to the RDF site. Of course the position of the transmitter

must be known accurately for each transmission.

#### Using RDF Antennas for Communications

Because of their directional characteristics, RDF antennas would seem to be useful for two-way communications. It has not

been mentioned earlier that the efficiency of receiving loops is poor. The radiation resistance is very low, and the resistance of wire conductors by comparison is significant. For this reason it is common to use some type of preamplifier with receiving loops. Small receiving loops can often be used to advantage in a fixed station, to null out either a noise source or unwanted signals.

A loop that is small in terms of a wavelength may also be used for transmitting, but a different construction technique is necessary. A thick conductor is needed at HF, several inches in diameter. The reason for this is to decrease the ohmic losses in the loop. Special methods are also required to couple power into a small loop, such as links. A small loop is highly inductive, and the inductance may be canceled by inserting a capacitor in series with the loop itself. The capacitor must be able to withstand the high RF currents that flow during transmissions.

The Adcock antenna and other phased arrays have been used extensively for transmitting. In this application maximum response is off the ends of the Adcock, which is 90° away from the null direction used for RDF work.

#### A PORTABLE FIELD-STRENGTH METER

Few amateur stations, fixed or mobile, are without need of a field-strength meter. An instrument of this type serves many useful purposes during antenna experiments and adjustments, and may be used for closing in on an RDF fix. When work is to be done from many wavelengths away, a simple wavemeter lacks the necessary sensitivity. Further, its linearity leaves much to be desired.

The field-strength meter described here takes care of these problems. Additionally,

it is small, measuring only  $4 \times 5 \times 8$  inches. The power supply consists of two 9-volt batteries. Sensitivity can be set for practically any amount desired. However, from a usefulness standpoint, the circuit should not be too sensitive or it will respond to unwanted signals. This unit also has excellent linearity with regard to field strength, which is very helpful in RDF work. (The field strength of a received signal varies directly with the distance from the source, all other things being equal.) The frequency range includes all amateur bands from 3.5 through 148 MHz, with band-switched circuits, thus avoiding the use of plug-in inductors. All in all, it is a quite useful instrument.

The unit is pictured in Figs. 15 and 16, and the schematic diagram is shown in Fig. 17. A type 741 op-amp IC is the heart of the unit. The antenna is connected to J1, and a tuned circuit is used ahead of a diode detector. The rectified signal is coupled as dc and amplified in the op amp. Sensitivity of the op amp is controlled by inserting R3 through R6 in the circuit by means of S2.

With the circuit shown, and in its most sensitive setting, M1 will detect a signal from the antenna on the order of  $100 \mu\text{V}$ . Linearity is poor for approximately the first 1/5 range of M1, but then is almost straight-line from there to full-scale deflection. The reason for the poor linearity at the start of the readings is because of nonlinearity of the diodes at the point of first conduction. If gain measurements are being made this is of no real importance, however, as accurate gain measurements can be made in the linear portion of the readings. For RDF measurements, just remember that the indicated strength is not proportional to the distance at the low end of the scale.

The 741 op amp requires both a positive and a negative voltage source. This is obtained by connecting two 9-volt batteries in series and grounding the center. One other feature of the instrument is that it can be used remotely by connecting an external meter at J2. This is handy if one wants to adjust an antenna and observe the results without having to leave the antenna site.

L1, the 80/40 meter coil, is tuned by C1. The coil is wound on a toroid form. For 20, 15 or 10 meters, L2 is switched in parallel with L1 to cover the three bands. L5 and C2 cover approximately 40 to 60 MHz, and L7 and C2 from 130 MHz to approximately 180 MHz. The two VHF coils are also wound on toroid forms.

#### Construction Notes

The majority of the components may be mounted on an etched circuit board. A shielded lead should be used between pin 4 of the IC and S2. The same is true for the leads from R3 through R6 to the switch. Otherwise, parasitic oscillations may occur in the IC because of its very high gain.

For the unit to cover the 144-MHz band, L6 and L7 should be mounted directly across the appropriate terminals of S1, rather than on a circuit board. The extra lead length adds too much inductance to the circuit. It isn't necessary to use toroid forms for the 50- and 144-MHz coils. They were used in the version described here simply because they were available. Air-wound coils of the appropriate inductance can be substituted.

#### Calibration

The field-strength meter can be used "as is" for a relative-reading device for RDF work. A linear indicator scale will serve admirably. However, it will be a much more useful instrument for antenna work if it is calibrated in decibels, enabling the user to check relative gain and front-to-back ratios. If one has access to a calibrated signal generator, it can be connected to the field-strength meter and different signal levels can be fed to the device for making a calibration chart. Signal-generator voltage ratios can be converted to decibels by using the equation

$$\text{dB} = 20 \log (V_1/V_2) \quad (\text{Eq. 1})$$

where  $V_1/V_2$  is the ratio of the two voltages, and log is the common logarithm.

Let's assume that M1 is calibrated evenly from 0 to 10. Next, assume we set the signal generator to provide a reading of 1 on M1, and that the generator is feeding a  $100\text{-}\mu\text{V}$  signal into the instrument. Now we increase the generator output to  $200 \mu\text{V}$ , giving us a voltage ratio of 2 to 1. Also let's assume M1 reads 5 with the  $200\text{-}\mu\text{V}$  input. From the equation above, we find that the voltage ratio of 2 equals 6.02 dB between 1 and 5 on the meter scale. M1 can be calibrated more accurately between 1 and 5 on its scale by adjusting the generator and figuring the ratio. For example, a ratio of  $126 \mu\text{V}$  to  $100 \mu\text{V}$  is 1.26, corresponding to 2.0 dB. By using this method, all of the settings of S2 can be calibrated. In the instrument shown here, the most sensitive setting of S2 with R3, 1 megohm, provides a range of approximately 6 dB for M1. Keep in mind that the meter scale for each setting of S1 must be calibrated similarly for each band. The degree of coupling of the tuned circuits for the different bands will vary, so each band must be calibrated separately.

Another method for calibrating the instrument is using a transmitter and measuring its output power with an RF wattmeter. In this case we are dealing with power rather than voltage ratios, so this equation applies:

$$\text{dB} = 10 \log (P_1/P_2) \quad (\text{Eq. 2})$$

where  $P_1/P_2$  is the power ratio.

With most transmitters the power output can be varied, so calibration of the test instrument is rather easy. Attach a pickup

antenna to the field-strength meter (a short wire a foot or so long will do) and position the device in the transmitter antenna field. Let's assume we set the transmitter output for 10 watts and get a reading on M1. We note the reading and then increase the output to 20 watts, a power ratio of 2. Note the reading on M1 and then use Eq. 2. A power ratio of 2 is 3.01 dB. By using this method the instrument can be calibrated on all bands and ranges.

With the tuned circuits and coupling links specified in Fig. 17, this instrument has an average range on the various bands of 6 dB for the two most sensitive positions of S2, and 15 dB and 30 dB for the next two successive ranges. The 30-dB scale is handy for making front-to-back antenna measurements without having to switch S2.

#### A SHIELDED LOOP WITH SENSING ANTENNA FOR 28 MHz

Fig. 18 shows the construction and mounting of a simple, shielded, 10-meter loop. The loop is made from an 18-inch length of RG-11/U (solid or foamed dielectric) secured to an aluminum box of any convenient size, with two coaxial cable hoods (Amphenol 83-1HP/U). The outer shield must be broken at the exact center. C1 is a 25-pF variable capacitor, and is connected in parallel with a 33-pF mica padder capacitor, C3. C1 must be tuned to the desired frequency while the loop is connected to the receiver in the same way as it will be used for RDF. C2 is a small differential capacitor used to provide electrical symmetry. The lead-in to the receiver is 67 inches of RG-59/U cable (82 inches if the cable has foamed dielectric).

The loop can be mounted on the roof of the car with a rubber suction cup. The builder might also fabricate some kind of bracket assembly to mount the loop temporarily in the window opening of the automobile, allowing for loop rotation. Reasonably true bearings may be obtained through the windshield when the car is pointed in the direction of the hidden transmitter. More accurate bearings may be obtained with the loop held out the window and the signal coming toward that side of the car.

Sometimes the car broadcast antenna may interfere with accurate bearings. Disconnecting the antenna from the broadcast receiver may eliminate this trouble.

#### Sensing Antenna

A sensing antenna can be added to the loop to check on which of the two directions indicated by the loop is the correct one. Add a phono jack to the top of the aluminum case shown in Fig. 18. The insulated center terminal of the jack should be connected to the side of the tuning capacitors connected to the center conductor of the RG-59/U coax feed line. The jack then takes a short vertical antenna rod of a diameter to fit the jack, or a piece of

Fig 18 — Sketch showing constructional details of the 28-MHz RDF loop. The outer braid of the coax loop is broken at the center of the loop. The gap is covered with waterproof tape, and the entire assembly is given a coat of acrylic spray.

no. 12 or 14 solid wire may be soldered to the center pin of a phono plug for insertion in the jack. The sensing antenna can be plugged in as needed. Starting with a length of about four times the loop diameter, the length of the sensing antenna should be pruned until the pattern is similar to Fig. 1D.

### LOOPSTICK ANTENNA FOR 1.8 MHz

Fig. 19 contains a diagram for a rod loop. The winding (L1) has the appropriate number of turns to permit resonance with C1 at the operating frequency. L1 should be spread over approximately 1/3 of the core center. Litz wire will yield the best Q, but Formvar magnet wire can be used if desired. A layer of 3M Company glass tape (or Mylar tape) is recommended as a covering for the core before adding the

wire. Masking tape can be used if nothing else is available.

L2 functions as a coupling link over the exact center of L1. C1 is a dual-section variable, although a differential capacitor might be better toward obtaining optimum balance (not tried). The loop Q can be controlled by means of C2, which is a mica compression trimmer.

Electrostatic shielding of rod loops can be effected by centering the rod in a U-shaped aluminum, brass or copper channel that extends slightly beyond the ends of the rod loop (1 inch is suitable). This idea is shown in Fig. 19B. The open side (top) of the channel can't be closed, as that would constitute a shorted-turn condition and render the antenna useless. This can be proved by shorting across the center of the channel with a screwdriver blade when the loop is tuned to an incoming signal.

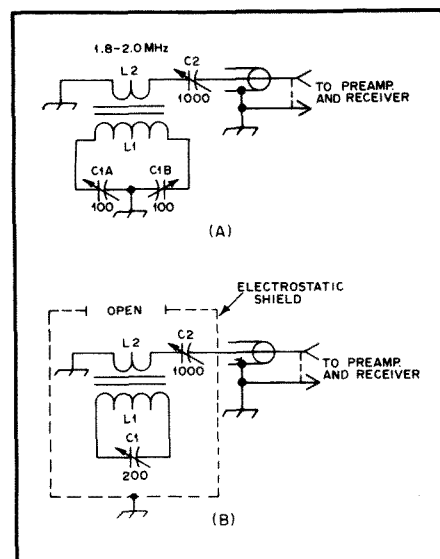

Fig. 19 — Diagram of a ferrite loop (A). C1 is a dual-section air variable. The circuit at B shows a rod loop contained in an electrostatic shield channel (see text). A low-noise pre-amplifier is shown in Fig. 22.

A photograph of a shielded rod loop is offered in Fig. 20. It was developed experimentally for 160 meters and uses two 7-inch ferrite rods that were glued end-to-end with epoxy cement. The longer core resulted in improved sensitivity during weak-signal reception.

### Obtaining a Cardioid Pattern

Although the bidirectional pattern of loop antennas can be used effectively in tracking transmitters down by means of triangulation, an essentially unidirectional loop response will help to reduce the time spent when doing so. Adding a sensing antenna to the loop is simple to do, and it will provide the desired cardioid response.

Fig. 21 shows how this can be accomplished. The link from the rod loop is connected via coaxial cable to the primary of T1, which is a tuned toroidal transformer with a split secondary winding. C3 is adjusted for peak signal response at the frequency of interest (as is C4), then R1 is adjusted for minimum back response of the loop. It will be necessary to readjust C3 and R1 several times to compensate for the interaction of these controls. The adjustments are repeated until no further null depth can be obtained. Tests show that null depths as great as 40 dB can be obtained with the circuit of Fig. 21 on 75 meters. A near-field weak-signal source was used during the tests.

The greater the null depth the lower the signal output from the system, so plan to include a preamplifier with 25 to 40 dB of gain. Q1 of Fig. 21 will deliver approximately 15 dB of gain. The circuit of Fig. 22 can be used following T2 to obtain an additional 24 dB of gain. In the interest of maintaining a good noise figure, even at 1.8 MHz, Q1 should be a low-noise

Fig. 20 — The shielded ferrite-rod loop for 160 meters. Two rods have been glued end to end (see text).

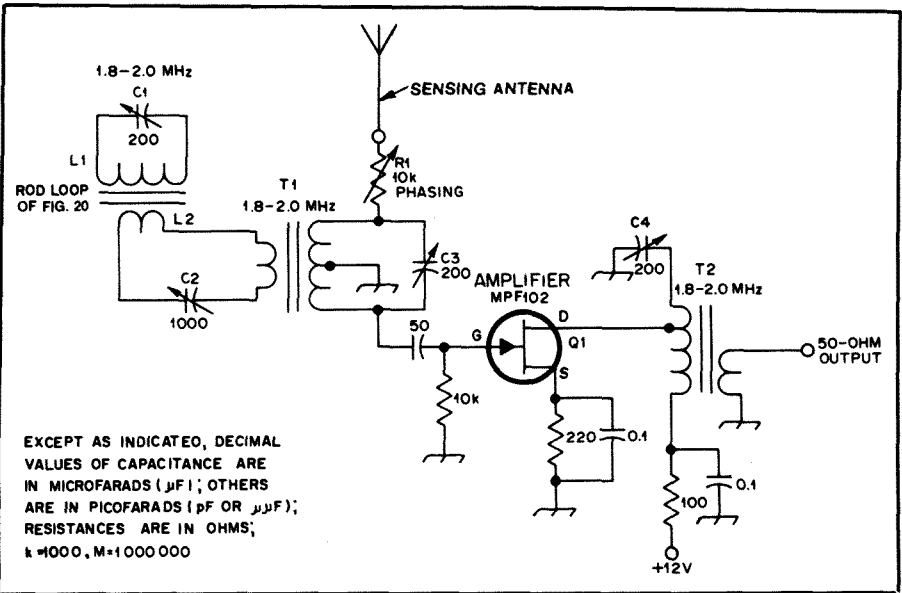

Fig. 21 — Schematic diagram of a rod-loop antenna with a cardioid response. The sensing antenna, phasing network and a preamplifier are shown also. The secondary of T1 and the primary of T2 are tuned to resonance at the operating frequency of the loop. T68-2 or T68-6 Amidon toroid cores are suitable for both transformers. Amidon also sells the ferrite rods for this type of antenna.

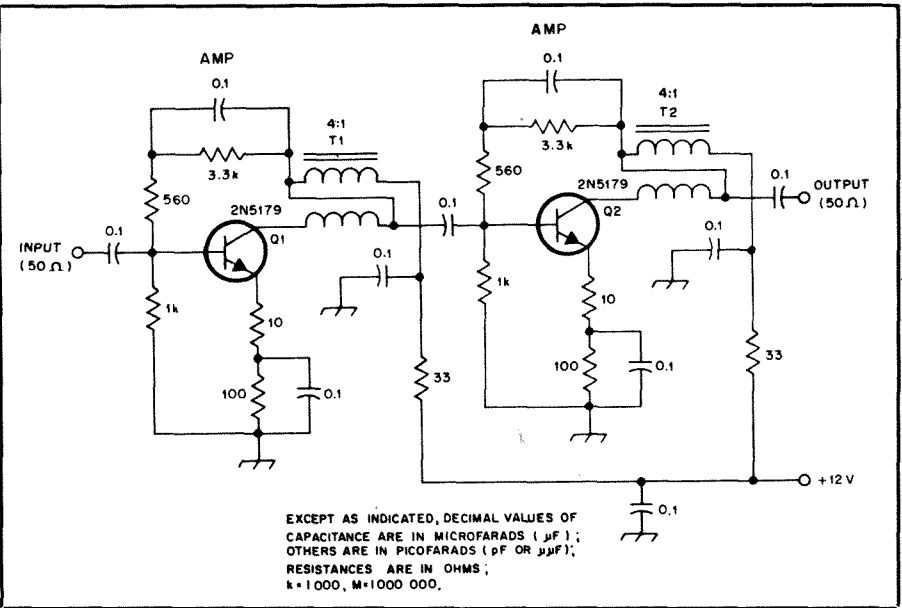

Fig. 22 — Schematic diagram of a two-stage broadband amplifier. T1 and T2 have a 4:1 impedance ratio and are wound on FT-50-61 toroid cores (Amidon) that have a  $\mu_i$  of 125. They contain 12 turns of no. 24 enam. bifilar wound wire. The capacitors are disc ceramic. This amplifier should be built on double-sided circuit board for best stability.

Fig. 23 — Unidirectional 75-meter RDF using ferrite-core loop with sensing antenna. Adjustable components of the circuit are mounted in the aluminum chassis supported by a short length of tubing.

device. A Siliconix U310 JFET would be ideal in this circuit, but a 2N4416, an MPF102 or a 40673 MOSFET would also be satisfactory.

The sensing antenna can be mounted 6 to 15 inches from the loop. The vertical whip need not be more than 12 to 20 inches long. Some experimenting may be necessary in order to obtain the best results. It will depend also on the operating frequency of the antenna.

### A LOOPSTICK FOR 3.5 MHz

Figs. 23 through 25 show an RDF loop suitable for the 3.5-MHz band. It uses a construction technique that has had considerable application in low-frequency marine direction finders. The loop is a coil wound on a ferrite rod from a broadcast-antenna loopstick. Because it is possible to make a coil of high Q with the ferrite core, the sensitivity of such a loop is comparable to a conventional loop that is a foot or so in diameter. The output of the vertical-rod sensing antenna, when properly combined with that of the loop, gives the system the cardioid pattern shown in Fig. 1D.

To make the loop, remove the original winding on the ferrite core and wind a new coil as shown in Fig. 24. Other types of cores than the one specified may be substituted; use the largest coil available and adjust the winding so the circuit resonates in the 75-meter band within the range of C1. The tuning range of the loop may be checked with a dip meter.

The sensing system consists of a 15-inch whip and an adjustable inductance that will resonate the whip as a quarter-wave antenna. It also contains a potentiometer to control the output of the antenna. S1 is used to switch the sensing antenna in and out of the circuit.

The whip, the loopstick, the inductance L1, the capacitor C1, the potentiometer R1

Fig. 24 — Circuit of the 75-meter direction finder.

C1 — 140 pF variable (125-pF ceramic trimmer in parallel with 15-pF ceramic fixed).  
 L1 — Approx. 140  $\mu$ H adjustable (Miller No. 4512 or equiv.)  
 R1 — 1-k $\Omega$  carbon potentiometer.  
 S1 — SPST toggle.

Loopstick — Approx. 15  $\mu$ H (Miller 705-A, with original winding removed and wound with 20 turns of no. 22 enam.). Link is two turns at center. Winding ends are secured with Scotch electrical tape.

Fig. 25 — Components of the 75-meter RDF are mounted on the top and sides of a Channel-lock type box. In this view R1 is on the left wall at the upper left and C1 is at the lower left. L1, S1 and the output connector are on the right wall. The loopstick and whip mount on the outside.

Fig. 26 — At A is a simple configuration that produces a cardioid pattern. At B is a convenient way of fabricating a sturdy mount for the radiator using BNC connectors.

and the switch S1 are all mounted on a 4  $\times$  5  $\times$  3-inch box chassis as shown in Fig. 25. The loopstick may be mounted and protected inside a piece of 1/2-inch PVC pipe. A section of 1/2-inch electrical conduit is attached to the bottom of the chassis box

and this supports the instrument.

To produce an output having only one null there must be a 90° phase difference between the outputs of the loop and sensing antennas, and the signal strength from each must be the same. The phase shift is obtained by tuning the sensing antenna slightly off frequency by means of the slug in L1. Since the sensitivity of the whip antenna is greater than that of the loop, its output is reduced by adjusting R1.

#### Adjustment

To adjust the system, enlist the aid of a friend with a mobile transmitter and find a clear spot where the transmitter and RDF receiver can be separated by several hundred feet. Use as little power as possible at the transmitter. (Remove your own transmitter antenna before trying to make any loop adjustments and remember to leave it off during transmitter hunts.) With the test transmitter operating on the proper frequency, disconnect the sensing antenna with S1, and peak the loopstick using C1, while watching the S meter on the receiver. Once the loopstick is peaked, no further adjustment of C1 will be necessary. Next, connect the sensing antenna and turn R1 to minimum resistance. Then vary the adjustable slug of L1 until a maximum reading of the S meter is again obtained. It may be necessary to turn the unit a bit during this adjustment to obtain a larger reading than with the loopstick alone. The last turn of the slug is quite critical, and some hand-capacitance effect may be noted.

Now turn the instrument so that one side (not an end) of the loopstick is pointed toward the test transmitter. Turn R1 a complete revolution; if the proper side was chosen a definite null should be observed on the S meter for one particular position of R1. If not, turn the RDF 180° and try again. This time leave R1 at the setting that produces the minimum reading. Now adjust L1 very slowly until the S-meter reading is reduced still further. Repeat this several times, first R1, and then L1 until

the best minimum is obtained.

Finally, as a check, have the test transmitter move around the RDF and follow it by turning the RDF. If the tuning has been done properly the null will always be broadside to the loopstick. Make a note of the proper side of the RDF for the null, and the job is finished.

#### A PHASED ARRAY FOR 144-MHz RDF WORK

Although there may be any number of different antennas that will produce a cardioid pattern, the simplest design is depicted in Fig. 26. Two 1/4-wavelength vertical elements are spaced one 1/4-wavelength apart and are fed 90° out of phase. Each radiator is shown with two radials approximately 5 percent shorter than the radiators.

During the design phase of this project a personal computer was used to predict the impact on the antenna pattern of slight alterations in its size, spacing and phasing of the elements. The results suggest that this system is a little touchy and that the most significant change comes at the null. Very slight alterations in the dimensions caused the notch to become much more shallow and, hence, less usable for RDF. Early difficulties in building a working model bore this out.

This means that if you decide to build this antenna, you will find it advantageous to spend a few minutes to tune it for the deepest null. If it is built using the techniques presented here, this should prove to be a small task that is well worth the extra effort. Tuning is accomplished by adjusting the length of the vertical radiators, the spacing between them and, if necessary, the lengths of the phasing harness that connects them. Tune for the deepest null on your S meter when using a signal source such as a moderately strong repeater. This should be done outside, away from buildings and large metal objects. Initial indoor tuning on this project was tried in the kitchen, which revealed that reflections off the appliances were producing spurious readings. Beware too of distant water towers, radio towers, and large office or apartment buildings. They can reflect the signal and give false indications.

Construction is simple and straightforward. Fig. 26B shows a female BNC connector (Radio Shack 278-105) that has been mounted on a small piece of PC-board material. The BNC connector is held "upside down" and the vertical radiator is soldered to the center solder lug. A 12-in piece of brass tubing provides a snug fit over the solder lug. A second piece of tubing, slightly smaller in diameter, is telescoped inside the first. The outer tubing is crimped slightly at the top after the inner tubing is installed. This provides positive contact between the two tubes. For 146 MHz the length of the radiators is calculated to be about 19 in.

You should be able to find small brass tubing at a hobby store. If none is available

Fig. 27 — The phasing harness for the 144-MHz RDF array. The phasing sections must be measured from the center of the T connector to the point that the vertical radiator emerges from shield portion of the upside-down BNC female. Don't forget to take the length of the connectors into account when constructing the harness. If care is taken and coax with polyethylene dielectric is used, you should not have to prune the phasing line. With this phasing system, the null will be in a direction that runs along the boom, on the side of the  $\frac{1}{4}$ -wavelength section.

Fig. 28 — A simple mechanical support for the DF antenna made of PVC pipe and fittings.

in your area, consider brazing rods. This is often available in hardware sections of discount stores. It will probably be necessary to solder a short piece to the top since these come in 18-in sections. Also, tuning will not be quite as convenient. Two 18-inch radials are added to each element by soldering them to the board. Two 36-in pieces of heavy brazing rod were used in this project.

### The Phasing Harness

As shown in Fig. 27, a T connector is used with two different lengths of coaxial line to form the phasing harness. This method of feeding the antenna is superior to other simple systems toward obtaining equal current in the two radiators. Un-

equal currents tend to reduce the depth of the null in the pattern, all other factors being equal.

With no radials or with two radials perpendicular to the vertical element, it was found that a  $\frac{1}{4}$ -wavelength section made of RG-59/U, 75- $\Omega$  coax produced a deeper notch than a  $\frac{1}{4}$ -wavelength section made of RG-58/U, 50- $\Omega$  line. However, with the two radials bent downward somewhat, the RG-58/U section seemed to outperform the RG-59/U. There will probably be enough variation from one antenna to the next that it will be worth your time and effort to try both sections and determine which works best for your antenna. The  $\frac{1}{2}$ -wavelength section can be made from either RG-58/U or RG-59/U because it should act as a 1-to-1 transformer.

The most important thing about the coax for the harness is that it be of the highest quality (well shielded and with a polyethylene dielectric). The reason for avoiding foam dielectric is that the velocity factor can vary from one roll to the next — some say it varies from one foot to the next in the same roll. Of course, it can be used if you have test equipment available that will allow you to determine its electrical length. Assuming you do not want to or cannot go to that trouble, stay with solid polyethylene-dielectric coax. Avoid coax that is designed for the CB market or the do-it-yourself cable-TV market. (A good choice is Belden 8240 for the RG-58/U or Belden 8241 for the RG-59/U.)

Both RG-58 and RG-59 with polyethylene dielectric have a velocity factor of 0.66. Therefore, for 146 MHz a quarter wavelength of transmission line will be  $19 \text{ in} \times 0.66 = 12.5 \text{ in}$ . A half-wavelength section will be twice this length or 25 in. One thing that you must take into account is that the transmission line is the total length of the cable and the connectors. Depending on the type of construction and the type of connectors that you choose, the actual length of the coax by itself will vary somewhat. You will have to determine that empirically.

Y connectors that mate with RCA phono plugs are widely available and the phono plugs are easy to work with. Avoid the temptation to substitute these for the T and BNC connectors. Phono plugs and a Y connector were tried. The results with that system were not satisfactory. The performance seemed to change from day to day and the notch was never as deep as it should have been. Although they are more difficult to find, BNC T connectors will provide superior performance and are well worth the extra effort. If you must make substitutions, it would be preferable to use UHF connectors (type PL-259).

Fig. 28 shows a simple support for the antenna. PVC tubing is used throughout. Additionally, you will need a T fitting, two end caps and possibly some cement. (By not cementing the PVC fittings together, you will have the option of

disassembly for transportation.) Cut the PVC for the dimensions shown with a saw or a tubing cutter. A tubing cutter is preferred because it produces smooth, straight edges and is less messy. Drill a small hole through the PC board near the female BNC of each element assembly. Measure 19 inches along the boom (horizontal) and mark the two end points. Drill a small hole vertically through the boom at each mark. Use a small nut and bolt to attach the element assembly to the boom.

### Tuning

The dimensions given throughout this section are those for approximately 146 MHz. If the signal you will be tracking is above that frequency, then the measurements will probably need to be a bit shorter. If you are to operate below that frequency, then they will need to be a little longer.

Once you have built the antenna to the rough size, the fun begins. You will need a signal source near the frequency that you will be using for your RDF work. Adjust the length of the radiators and the spacing between them for the deepest null on your S meter. Make changes in increments of  $\frac{1}{4}$  in or less. If you must adjust the phasing line, make sure that the  $\frac{1}{4}$ -wavelength section is exactly one-half the length of the half-wavelength section. Keep tuning until you have a satisfactorily deep null on your S meter.

### AN ADCOCK ANTENNA

While loops are adequate in applications where only the ground wave is present, the question arises of what can be done to improve the performance of an RDF system for sky-wave reception. One type of antenna that has been used successfully for this purpose is the Adcock antenna. There are many possible variations, but the basic configuration is shown in Fig. 29.

The operation of the antenna when a vertically polarized wave is present is very similar to a conventional loop. As can be seen from Fig. 29, currents  $I_1$  and  $I_2$  will be induced in the vertical members by the passing wave. The output current in the transmission line will be equal to their difference. Consequently, the directional pattern will be identical to the loop with a null broadside to the plane of the elements and with maximum gain occurring in end-fire fashion. The magnitude of the difference current will be proportional to the spacing,  $d$ , and the length of the elements. Spacing and length are not critical, but somewhat more gain will occur for larger dimensions than for smaller ones. In an experimental model, the spacing was 21 feet (approximately 0.15 wavelength on 40 meters) and the element length was 12 feet.

Response of the Adcock antenna to a horizontally polarized wave is considerably different from that of a loop. The currents induced in the horizontal members (dotted

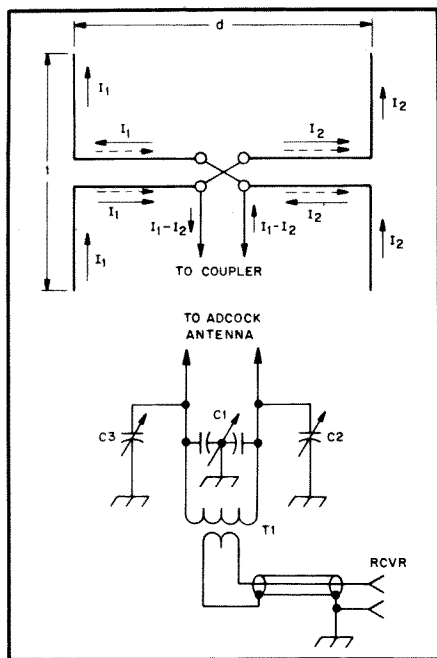

Fig. 29 — A simple Adcock antenna and suitable coupler (see text).

arrows in Fig. 29) tend to balance out regardless of the orientation of the antenna. This effect seemed to be borne out in practice, since good nulls were obtained with the experimental model under sky-

wave conditions that produced only poor nulls with small loops (both conventional and ferrite-loop models). Generally speaking, the Adcock antenna has very attractive properties with regard to amateur RDF applications. Unfortunately, its portability leaves something to be desired, and it is more suitable to fixed or semi-portable applications. While a metal support for the mast and boom could be used, wood is preferable because of its nonconducting properties. Less distortion of the pattern should result.

Since a balanced feed system is used, a coupler is required to match the unbalanced input of the receiver. It consists of T1 which is an air-wound coil with a two-turn link wrapped around the middle. The combination is then resonated to the operating frequency with C1. C2 and C3 are null-clearing capacitors. A low-power signal source is placed some distance from the Adcock antenna and broadside to it. C2 and C3 are then adjusted until the deepest null is obtained.

The coupler can be placed on the ground below the wiring-harness junction on the boom and connected by means of a short length of 300-ohm twin-lead. A piece of aluminum tubing was used as a mast, but in a practical application it could be replaced with a length of PVC tubing extending to the ground. This would facilitate rotation and would provide a means of at-

taching a compass card for obtaining bearings.

# Interference

**R**adio Frequency Interference (RFI): It is a jungle out there! Not a jungle of wildlife and tangled undergrowth, however. It is a jungle of electrical and electronic equipment, each piece of which is a potential source or victim of RFI, or both! Today, a host of new devices are creating an increasingly complex RF environment. Each new gadget brings with it a new set of problems to the residential community.

### The Electronic Home

Let's look around a perhaps "not-so-average" home. In the kitchen the blender whirrs and the microwave oven digital timer counts down to the blinking of the Public Service scanner. The wireless intercom emits a mild protest to the electronic activity. In the bathroom a family member is using a hair dryer and a portable radio. Both items are plugged into a ground-fault interrupter outlet.

In a quiet room supplied with mood lighting from an electronically controlled lamp, a color TV set is showing a movie that is delivered by cable. A video cassette recorder (VCR) records another program for later viewing.

One of the older children is in a bedroom doing homework on a microcomputer. Music is coming from the stereo record player in the corner. In the next bedroom a younger family member finds amusement in the video game connected to a portable TV set.

In the hall a pager sits in the battery charger just below a smoke detector. Someone had decided to place a call on the cordless telephone from this secluded spot.

Down in the basement, the water heater has turned on under control of the thermostat. Another thermostat, located upstairs, has called for hot air. The fuel oil gun is running in the furnace (as is the continuous ignition system) — the air is just now hot enough that a sensor starts the circulation blower. Mounted on the wall next to the power distribution box is the doorbell transformer.

Out in the garage the power tools and lawn mower silently wait for someone to use them. The garage door opener waits for a signal to be decoded by the receiver. Outside a loud sound will activate a fixture, turning on an outdoor light. When the family is away, the premises are guarded by an electronic security system. The system has a microwave intrusion detector; alarms are electronically reported over the telephone line.

Every device mentioned in this account has the potential of being either a source or victim of RFI — or both! Many other possibilities exist in the residential environment these days. Even the plumbing and wiring can conduct, radiate or rectify RF emanations from whatever source. And every month some new electronic "whiz bang" finds its way into our homes.

### A Technical Problem

Interference is a technical problem. The causes and cures are often straightforward, but they can be mysterious and complicated. Interference side effects have economic and political impact. Experience has shown that nearly all RFI problems experienced with home-entertainment devices result from basic design deficiencies in these devices. The few small components or filters that would prevent RFI are often left out of otherwise well-designed products as manufacturers attempt to reduce costs, and hence to reduce the prices of their products.

Interference is primarily a matter of emanation (sending) and interception (receiving). Unwanted emanations occur by radiation (as from an antenna) or conduction (as along a wire). How and where to treat unwanted emanation or interception will depend on where and how it occurs. If interfering harmonics are generated in a transmitter and are radiated by the station antenna, usually a filter in the feed line will solve the problem. If a TV set lacks immunity to the radio frequency environment, various types of filters can be used to cure the problem.

The source of the energy is not always the cause of interference; the actual cause is sometimes difficult to determine. Interfering harmonics or spurious emissions of an Amateur or CB Radio signal may be generated in the transmitter, in a bad (rectifying) connection in the antenna system, in the affected receiver RF amplifier (pre-amplifier) or in any poor metallic connection in the vicinity of the transmitter antenna. For that reason, the cause is usually discovered through a process of elimination. Usually, more than one action will be necessary to cure the problem.

The usual procedure for dealing with harmonically related interference calls for filters to be installed at the transmitter and the receiver. That treatment usually solves the problem; if it doesn't, try using direction-finding techniques on a harmonic of the offending signal.

Radio amateurs have traditionally been involved with the analog world — a realm of sine waves and distinct frequencies. Digital equipment can be found in almost every home and ham shack. The digital domain is a realm of square waves.

The frequency spectra of sine and square waves of the same fundamental frequency are quite different, as shown in Fig. 1. The sine wave is ideally represented by a single frequency. In contrast, an ideal square wave consists of a fundamental frequency plus an infinite series of odd harmonics. It is these harmonics that require proper treatment in digital circuits to prevent RF emanations. Treatment, which must be applied to the digital circuit and enclosure, generally consists of proper shielding, filtering and bypassing. The measures that help minimize the possibilities that a digital device will be a source of interference will also protect it from being a victim of interference.

### What's Being Done About RFI?

Along with the growth of new appliances in the electronic home come new regulations to deal with accompanying RFI

(A)

(B)

(C)

(D)

Fig. 1 — Time domain (oscilloscope) displays of a sine wave (A) and a square wave (B). Frequency-domain or spectral (spectrum-analyzer) displays of a sine wave (C) and a square wave (D). Vertical divisions in the spectral displays are 10 dB. With second-harmonic energy down 67 dB, the sine wave can be considered spectrally clean. By contrast, the square wave shows considerable energy in odd-order harmonics.

troubles. FCC rules now deal specifically with such services and devices as CATV, computers, cordless telephones and security devices. Although Public Law 97-259 gives the FCC authority to set standards for home-entertainment devices, the current approach looks toward voluntary compliance in place of legislation. Television sets and Amateur Radio equipment of recent vintage are, for the most part, superior to earlier models. Some VCRs still show a lack of RF immunity.

Cable television (CATV) is regulated by Parts 15 and 76 of the FCC rules. The Commission defines a CATV system as a "nonbroadcast facility" — a plant consisting of cables that carry television programming to subscribers. Cable television offers the amateur service several advantages over conventional reception. Signal levels on the cable are at a higher level than normally received "off air." This effectively eliminates fringe area (weak

signal) reception. In addition, these signals are supplied on a shielded cable, which further reduces the susceptibility to interference.

In the field, however, signals may leak from these ostensibly "closed" systems. When this leakage occurs, harmful interference to over-the-air services can occur. The FCC has specified the maximum allowable leakage from cable systems.

Section 76.613 regulates interference from CATV systems. Paragraph (a) defines harmful interference as "any emission, radiation or induction which endangers the functioning of a radio-navigation service or of other safety services or *seriously degrades, obstructs or repeatedly interrupts a radiocommunication service operating in accordance with this chapter*" (emphasis added). Paragraph (b) says "the operator of a cable television system that causes harmful interference shall promptly take appropriate measures

to eliminate the harmful interference."

Section 76.605(a)(12) spells out the limits for allowable radiation from a CATV system:

Frequencies	Radiation Limit ( $\mu\text{V}/\text{m}$ )	Distance (Feet)
Up to and including 54 MHz	15	100
Over 54 up to and including 216 MHz	20	10
Over 216 MHz	15	100

RF emanating from digital devices such as computers, and other incidental radiation devices such as power lines, industrial machines and electrical fences, are regulated in Part 15 of the FCC rules. Communication devices such as cordless telephones, FM wireless microphones and

other low-power appliances are also covered in Part 15. These devices may not cause harmful interference to other radio service communications. In addition, specifications for limits on amounts of RF energy emanating from a given device are included. For example, the wireless microphones mentioned earlier in this paragraph may not exceed certain field strengths.

Also, units (such as most 1.7-MHz cordless telephones) that operate under a waiver of the field strength requirements are controlled in another manner: These units must not exceed standards for RF current in the power and telephone lines.

Radiation limits also apply to personal computers manufactured after January 1, 1981. In many cases, labeling, identification and FCC certification are required for devices covered in Part 15. These requirements help ensure that the device operator understands the nature of the unit, and his or her obligations under the rules. For applicable excerpts of Part 15 or Part 76 of the Commission's rules, contact ARRL Headquarters.

Government regulation is not a panacea, however. We are in a period of shrinking government involvement in the life of the

society it governs. Thus, we have seen deregulation on the part of an FCC determined to let marketplace forces resolve their differences. And, with the FCC budget greatly reduced, we are witnessing a Commission less able to enforce the rules. Government rules are a help, but not the sole solution to RFI.

Help is available from other quarters as well. Manufacturers and professional trade associations are aware of the RFI phenomenon. While these organizations are not in positions to dictate policies to members, they can promote the need for responsibility in manufacturing and operations. Associations often publish pamphlets and manuals for their members explaining how they can make products less susceptible to RFI problems. The same associations lobby the government on behalf of their members.

The ARRL, as the principal membership organization of the amateur community, is ready to assist. The League publishes *Radio Frequency Interference: How to Identify and Cure It*, a guide with practical ideas and tips to bring harmony back to a neighborhood troubled with RFI. ARRL Headquarters is also the home of the

Technical Information Service (TIS). Members can call or write the TIS with their RFI questions. See Fig. 2A. CATVI complaints should be submitted on the form shown at Fig. 2B. *QST* publishes articles with timely information on the evolving RFI picture.

ARRL is also active on the legislative front. The League worked hard for passage of the Goldwater-Wirth measure (P.L. 97-259). In January 1982, ARRL filed a petition for rulemaking with the FCC to have CATV vacated from channels coinciding with amateur frequencies. This action was in response to membership concern over the problem of leakage and interference from "closed" cable TV systems.

An Official Observer (OO) program has been part of the ARRL field organization for more than half a century. First conceived in 1926, the OO Program was designed to "help brother amateurs by calling attention to violations of good practice...in the right way...in better operating...and ham enjoyment."

One of the significant aspects of Public Law 97-259 (known as the Communications Amendments Act of 1982 before being signed into law in September 1982)

Fig. 3 — Relationships of HF and VHF amateur bands to frequencies used in consumer electronic devices. The CATV channels are used in closed systems, but experience has shown these systems to have poor isolation from outside signals.

is one that authorizes the FCC to formally enlist the use of amateur volunteers in monitoring the airwaves for rules discrepancies or violations. (The same legislation paved the way for the Volunteer Examiner program.) Before approving the volunteer monitoring program, FCC's Field Operations Bureau (FOB) fully recognized the value of the organized and disciplined Amateur Radio community through the ARRL.

To fully utilize the ARRL Field Organization structure, the FOB has specifically indicated that the volunteer-monitoring program should be compatible with the amateur organizational structure. To this end, FOB created an Amateur Auxiliary (similar to those of the Civil Air Patrol and the Coast Guard Auxiliary). The Amateur Auxiliary/OO program is administered by the League's Section Managers and OO/RFI Coordinators, with support from ARRL Hq. For more information on the Amateur Auxiliary, see "The Amateur Auxiliary for Volunteer Monitoring," in August 1984 *QST*.

### What Can You Do?

**Be informed** — read, report, experiment and test. As an ARRL member, you will have access to publications that contain a wealth of information about RFI. Further, a skilled Headquarters staff stands ready to assist you.

**Report** — January 1, 1984 marked the beginning of the ARRL interference reporting system. All RFI reports/complaints are placed into a computer data base, to help locate and cure chronic interference problems. Use the format shown in Fig. 2 to document your report. Call or write the League's Technical Information Service with all requested information. If a chronic problem exists, we will probably have a cure on file. Similarly, if you experience a problem and find the cure, let your League know about it! Additional report forms are available from Headquarters for an s.a.s.e.

**Experiment and test** — RFI problems and solutions are not always simple. Try the usual; then try the unusual. It is also possible that more than one action will be necessary to cure the problem. This chapter will help you with ideas.

**Be cooperative** — the first step is to ensure that your station is assembled and operated according to "good engineering and amateur practice." Check your transmitter; try using a low-pass filter. Then, check your own TV set for problems. Put your own house in order before checking on your neighbor's.

**When approaching your neighbor**, bear in mind that he or she likely knows little of radio or RFI. Proceed accordingly. Explain your interpretation of the situation in simple terms. Then, politely make your recommendations. Neighborhood RFI disputes are settled when a cooperative atmosphere exists.

**Be communicative** — contact the manu-

facturer of the offending equipment. Many responsible manufacturers have a policy of supplying filters for eliminating television interference when such cases are brought to their attention. A list of those manufacturers, and a more thorough treatment of the RFI problem, can be obtained by writing the ARRL. If a given manufacturer is not listed, it is still possible that he can be persuaded by writing either directly to the manufacturer or to the Electronic Industries Association (EIA).<sup>1</sup>

Similarly, if the problem lies with a CATV operator, public utility or other facility, let the responsible party know about it. You will often find assistance in your efforts to track down an RFI source.

If an RFI problem appears to be a violation of FCC rules, and there is no response to your requests for corrective action, contact your nearest FCC district office. See *The FCC Rule Book* or the *License Manual*, both published by ARRL, for the address.

Don't forget to communicate your RFI problems and solutions to League Headquarters. The ARRL RFI Task Group needs a complete and accurate picture of the ever-changing RFI scene so it can make appropriate policy recommendations to the ARRL Board of Directors.

### Dealing With Interference

Many interference problems are caused by harmonics. Fig. 3 is a chart showing the frequency relationships between broadcast channels and amateur harmonics.

The visible effects of interference vary with the type and intensity of the interference. Blackout, where the picture and sound disappear completely, leaving the screen dark, occurs only when the transmitter and receiver are close together. Strong interference ordinarily causes the picture to be broken up, leaving a jumble of light and dark lines, or turns the picture "negative" — the normally white parts of the picture turn black and the normally black parts turn white.

Cross-hatching — diagonal bars or lines in the picture — often occurs as well, and also represents the most common type of less severe interference. The bars are the result of the beat between the harmonic frequency and the picture carrier frequency. They are broad and relatively few in number if the beat frequency is comparatively low — near the picture carrier — and are numerous and very fine if the beat frequency is very high — toward the upper end of the channel. Typical cross-hatching is shown in Fig. 4A.

Whether or not cross-hatching is visible, an amplitude-modulated transmitter may cause sound bars in the picture. These are

shown in Fig. 4B. They result from the variations in the intensity of the interfering signal when modulated. Under most circumstances modulation bars will not occur if the amateur transmitter is frequency- or phase-modulated. With these types of modulation the cross-hatching will wiggle from side to side with the modulation.

Except in the more severe cases, there is seldom any effect on the sound reception when interference shows in the picture, unless the frequency is close to the sound carrier. In this event the sound may be interfered with even though the picture is clean.

Reference to Fig. 3 will show whether or not harmonics of the frequency in use will fall in any television channels that can be received in the locality. It should be kept in mind that not only harmonics of the final frequency may interfere, but also harmonics of any frequencies that may be present in mixer or frequency-multiplier stages. In the case of 144-MHz transmitters, frequency-multiplying combinations that require a doubler or tripler stage to operate on a frequency in a low-band VHF channel in use in the locality should be avoided.

### Harmonic Suppression

Effective harmonic suppression has three separate phases:

- 1) Reducing the amplitude of harmonics generated in the transmitter. This is a matter of circuit design and operating conditions.

- 2) Preventing stray radiation from the transmitter and associated wiring. This requires adequate shielding and filtering of all circuits and leads from which radiation can take place.

- 3) Preventing harmonics from being fed into the antenna.

It is impossible to build a transmitter that will not generate some harmonics. It is advantageous to reduce harmonic strength through circuit design and choice of operating conditions before attempting to prevent harmonics from being radiated. Harmonic radiation from the transmitter itself or from its associated wiring obviously will cause interference just as readily as radiation from the antenna. Measures taken to prevent harmonics from reaching the antenna will not reduce TVI if the transmitter itself is radiating harmonics. But once it has been found that the transmitter itself is free from harmonic radiation, devices for preventing harmonics from reaching the antenna can be expected to produce results.

### Reducing Harmonic Generation

Since reasonably efficient operation of RF power amplifiers always is accompanied by harmonic generation, good judgment calls for operating all frequency-multiplier stages at a very low power level. When the final output frequency is reached, it is desirable to use as few stages as possible

(A)

(B)

Fig. 4 — At A, cross-hatching caused by the beat between the picture carrier and an interfering signal inside the TV channel. At B, sound bars or modulation bars accompanying amplitude modulation of an interfering signal. In this case the interfering carrier is strong enough to destroy the picture, but in mild cases the picture is visible through the horizontal bars. Sound bars may accompany modulation even though the unmodulated carrier gives no visible cross-hatching.

Fig. 5 — A VHF resonant circuit is formed by the tube capacitance and the lead inductances through the tank and blocking capacitors. Regular tank coils are not shown, since they have little effect on such resonances. C1 is the grid tuning capacitor and C2 is the plate tuning capacitor. C3 and C4 are the grid and plate blocking or bypass capacitors, respectively.

in building up to the final output power level and to use devices that require minimum drive power.

### Circuit Design and Layout

Harmonic currents of considerable

<sup>1</sup>Electronic Industries Association, 2001 Eye St., N.W., Washington, DC 20006. Attention: Director of Consumer Affairs.

Fig. 6 — This coax shield decoupler is made with steel wool stuffed into an IBM copier tube. This size was selected for photographic purposes, but to be effective, the device should be about twice as long.

amplitude flow in both the input and output circuits of RF power amplifiers, but they will do relatively little harm if they can be efficiently bypassed to the cathode, emitter or source of the active device. Fig. 5 shows the paths followed by harmonic currents in an amplifier circuit. Because of the high reactance in the tank coil, there is little harmonic current in it, so the harmonic currents simply flow through the tank capacitor, the input or output blocking capacitor and the device interelectrode capacitances. The lengths of the leads forming these paths is of great importance, since the inductance in this circuit will resonate with the interelectrode capacitance in the VHF range. Generally, only the interelectrode capacitance is considered in this respect, because of the relatively large values of capacitance contained in the blocking and tank circuitry. If such a resonance happens to fall near the same frequency as one of the transmitter harmonics, the effect is the same as though a harmonic tank circuit had been deliberately introduced; the harmonic at that frequency would be tremendously increased in amplitude.

Such resonances are unavoidable, but by keeping the path from plate to cathode and from grid to cathode (and between corresponding terminals in solid-state devices) as short as possible, the resonant frequency can usually be raised above 100 MHz in amplifiers of medium power. This places the harmonic energy where it will cause minimal interference.

It is easier to place grid-circuit VHF resonances where they will do no harm when the amplifier is link-coupled to the driver stage, since this generally permits shorter leads and more favorable conditions for bypassing the harmonics than is the case with capacitive coupling. Link coupling also reduces the coupling between the driver and amplifier at harmonic frequencies, thus preventing driver harmonics from being amplified.

The inductance of leads from the tube to the tank capacitor can be reduced not only by shortening but by using flat strap instead of wire conductors. It is also better to use the chassis as the return from the blocking capacitor or tuned circuit to

cathode, since the chassis path will have less inductance than almost any other form of connection.

The VHF resonance points in amplifier tank circuits can be found by coupling a dip meter covering the 50-250 MHz range to the grid and plate leads. If a resonance is found in or near a TV channel, methods such as those described above should be used to move it well out of the TV range. The dip meter also should be used to check for VHF resonances in the tank coils, because coils made for 14 MHz and below usually will show such resonances. In making the check, disconnect the coil entirely from the transmitter and move the dip meter coil along it while exploring for a dip in the 54- to 88-MHz band. If a resonance falls in a TV channel that is in use in the locality, changing the number of turns will move it to a less-troublesome frequency.

### Operating Conditions

Grid bias and grid current have an important effect on the harmonic content of the RF currents in both the grid and plate circuits. In general, harmonic output increases as the grid bias and grid current are increased, but this is not necessarily true of a particular harmonic. The third and higher harmonics, especially, will go through fluctuations in amplitude as the grid current is increased, and sometimes a high value of grid current will minimize one harmonic as compared with a low value. This characteristic can be used to advantage where a particular harmonic is causing interference; however, operating conditions that minimize one harmonic may greatly increase another.

### Suppression Practices

Complete elimination of TVI is often not a simple process. It seldom happens that a single measure such as installing a high-pass filter at the TV set will cure the problem. Rather, a number of methods must be applied simultaneously. The principal factor in any TVI situation is the ratio of TV signal strength to interference level. This includes interference of all types such as ignition noise, random or thermal noise (which isn't really interference but sets the minimum signal that permits snow-free reception), and unwanted signals that fall within the TV channel. A signal-to-interference ratio greater than approximately 35 to 40 dB is required for good picture quality.

In this regard, an area frequently overlooked in TVI difficulties is the TV antenna. A poor antenna with little gain in the direction of the TV station, old and corroded wire, and connections (which can cause the harmonic generation by rectification of a clean signal generated in a nearby amateur transmitter), may result in a TVI situation that is impossible to solve. Generally speaking, if the picture quality on the TV set experiencing the interference

is poor to begin with, even sophisticated suppression measures are likely to prove futile. In such cases, the only solution is replacement of the defective TV antenna system components. Corroded and cracked lead-in cables should be replaced, and the antenna terminals cleaned. If the TV antenna shows signs of corrosion and/or deterioration, it should also be replaced. Note: The amateur has no legal or financial responsibility to pay for the replacement of the antenna system — such replacement is the responsibility of the TV owner.

### Grounds

Grounding of equipment has long been considered a first step in eliminating interference. While the method is very effective in the MF range and below, for all practical purposes it is useless in suppressing VHF energy. This is because even short lengths of wire have considerable reactance at VHF. For instance suppose a length of wire by itself has an inductance of 1  $\mu$ H. At 550 kHz, the reactance would be about 3.46 ohms. On the other hand, the same wire would have a reactance of over 300 ohms at 56 MHz, which is in the frequency range of TV channel 2. (Actually, the impedance of a wire becomes a more complicated entity to define at VHF. The delay effects along the wire are similar to those on the surface of an antenna. Consequently, the wire might even appear as an open circuit rather than as a ground as the electrical length approaches a quarter wavelength.)

From a shock-hazard point of view, grounding is important. However, never connect a ground *for any reason* to the chassis of a TV set. This is because many TV sets derive their operating voltages directly from the ac-service line. Although a schematic diagram of a TV set may indicate a power transformer is being used, caution should be exercised to be sure it is actually being employed for this purpose. Often, the only voltage the transformer is supplying is for the TV picture tube filament.

### Shielding

Effective shielding is perhaps the single most important measure in preventing or curing any RFI problem. However, unwanted RF energy must be dissipated. The task becomes harder to perform when the spacing between the source of energy and the boundaries of the shield diminish. Consequently, the use of a double shield is one way of reducing residual radiation from the primary shielding surface.

In order to obtain maximum effectiveness of a particular shielding measure, no breaks or points of entry should be permitted. Small holes for ventilation purposes usually do not degrade shielding effectiveness. But even here, a honeycomb type of duct is often employed when maximum isolation is required. (A parallel bundle of small tubing has very high attenuation since

Fig. 7 — Winding the cable on a ferrite toroid is an effective shield current suppressor in some cases. Reversing the winding as pictured allows more turns with less shunt capacitance. RG-58 will suffice for moderate power applications. The most important property of the cable is complete shielding — avoid "bargain" cable having less than 95-percent braid coverage.

Fig. 8 — A large metallic baffle inhibits waves propagating on the outside of a coaxial cable. For VHF TV channel 2, the smallest effective baffle is a 9-foot-diameter circle, but the required size decreases linearly with frequency.

each tube by itself acts as a waveguide below cutoff.)

The isolation of a coaxial cable can be degraded considerably unless the ends of the shield are terminated properly. A braid should be soldered so it completely encloses the inner conductor(s) at the connector junction. For instance, the practice of twisting the braid and point soldering it to the base of a connector may result in a 20-dB degradation in isolation. Normally, this effect is not serious if the cable is run through an area where sensitive circuits don't exist. However, the isolation afforded by a filter can be reduced considerably in circuits where such cable breaks occur.

One instance where a shield break causes a serious problem is in the connection between the antenna terminals on a TV set and the tuner. Newer sets have a 75-ohm coaxial input along with a balun for 300-ohm line. However, because many TV sets have direct connections to the ac line, a decoupling network is used. The shielded lead to the tuner is broken and a capacitor is connected in series with the braid. This provides a low-impedance path for RF energy while presenting a high impedance at 60 Hz. Consequently, because of the cable break, high-pass filters at the antenna input terminals are not as effective as those built into the tuner itself.

### Coax Shield Chokes

As mentioned previously, VHF currents flowing on the outside of coaxial cables are frequently the cause of RFI. Figs. 6, 7 and 8 show techniques for reducing or eliminating conducted chassis radiation from coaxial cables. The cardboard tube stuffed with steel wool in Fig. 6 works on the absorption principle. The steel wool is very lossy and dissipates the RF energy on the shield. The tube pictured is 18 inches long. A longer tube would be even more effective.

Fig. 7 shows a choke wound on a ferrite toroidal core. Another coax radiation-suppression device is illustrated in Fig. 8. If the plate is at least a half wavelength (at the harmonic frequency to be suppressed) on its smallest dimension, it will provide a very effective barrier. Large pieces of sheet metal are expensive, so the baffle can be made from a sheet of cardboard or Masonite® covered with aluminum foil. The ideal placement of any of these chokes will vary with the standing wave pattern on the coax shield, but in general they should be close to the transmitter. Like all RFI remedies, the effectiveness of these devices varies widely with each interference situation. Therefore, one should not expect miracles. A coax shield choke installed at a TV receiver prevents signals picked up on the coax braid from reaching the tuner.

### Capacitors at RF

Capacitors are common elements found in almost any piece of electronic gear. However, some precautions are necessary when they are employed in RFI-preventive devices such as filters and in bypassing applications. In particular, lead inductance may be sufficient to resonate with the capacitor and cause the entire combination to have a high inductive reactance rather than the desired capacitive reactance.

This effect is illustrated in the accompanying photographs. The response curve shown in Fig. 9A is for a 10-MHz low-pass filter arranged in a "pi" configuration. However, this particular circuit realization required some large-value capacitors. Using ordinary capacitor types resulted in an unwanted resonance as evidenced by the sharp dip in the response curve at approximately

Fig. 9 — Stray lead inductance of a capacitor can degrade filter performance.

15 MHz. However, by going to the equivalent T configuration (see the section on filters in Chapter 2, on electrical laws and circuits), a circuit realization for the desired response required much smaller capacitance values. The curve shown in Fig. 9B approximated this response closely, and no

Fig. 11 — The FCC specifies that the spurious signals generated by transmitting equipment must be reduced well below the level of the fundamental. This graph illustrates exactly how far the spurious components must be reduced. This applies to amateur transmitters operating below 30 MHz.

may flow in the transmitter chassis and back into the ac line. A rig hot with RF or even the presence of broadcast harmonics while receiving may indicate a problem of this sort. In the case where you are using an antenna that requires a ground (such as an end-fed wire), never use any part of the ac conduits, water systems or other conductors in a building. It is always advisable to have a separate ground system for the antenna itself.

It is also good practice to use an antenna-matching network with no direct connection between the transmitter and antenna feed line. Any matching network that uses mutual-magnetic coupling exclusively will fulfill this requirement. Antenna pattern is another factor to consider; try to choose a type that directs the minimum possible signal into other dwellings. For instance, ground-mounted vertical antennas have considerable low-angle radiation, while a dipole directs energy at angles below the horizontal plane. A ground plane or beam mounted on as high a tower as practical will generally be better from an RFI and TVI standpoint than antennas closer to the ground.

#### FCC Rules Concerning RFI

Part 97.73 of the U.S. amateur regulations specifies the amateur's responsibility for signal purity:

(a) Except for a transmitter or transceiver built before April 15, 1977 or first marketed before January 1, 1978, the mean power of any spurious emission or radiation from an amateur transmitter, transceiver, or external radio frequency power amplifier being operated with a carrier frequency below 30 MHz shall be at least 40 decibels below the mean power of the fundamental without exceeding the power of 50 milliwatts. For equipment of mean power less than five watts, the attenuation shall be at least 30 decibels.

(b) Except for a transmitter or transceiver built before April 15, 1977 or first marketed before January 1, 1978, the mean power of any

effects of parasitic inductance were noticeable. To design a filter, it is advisable to compute the component values for as many configurations as possible in order to determine which one results in the most practical elements. If large capacitance values are unavoidable, either special low-inductance types should be used, or a number of ordinary smaller-value capacitors can be paralleled to reduce the effect of lead inductance.

A very desirable capacitor from an RFI point of view is C2 in Fig. 10. Instead of having two or more plates arranged in a parallel fashion, the conductors are coax-

ial and are separated by the dielectric. Such feedthrough capacitors are highly recommended for conducting leads in and out of circuits where the radiation of harmonic energy is possible. In addition, the RFC illustrated in Fig. 10 could consist of either a small coil wound over a composition resistor as shown or a ferrite bead on a straight piece of wire.

#### Decoupling from the AC Line

Direct feedback of RF energy into the ac power service is usually not a problem with modern transmitting equipment. However, currents induced on the antenna feed line

Fig. 12 — This graph illustrates to what level spurious-output energy must be reduced for equipment designed to operate in the 30- to 225-MHz range.

Fig. 13 — Schematic diagram showing component values of an experimental elliptic-function filter.

spurious emission or radiation from an amateur transmitter, transceiver, or external radio frequency power amplifier being operated with a carrier frequency above 30 MHz but below 225 MHz shall be at least 60 decibels below the mean power of the fundamental. For a transmitter having a mean power of 25 watts or less, the mean power of any spurious radiation supplied to the antenna transmission line shall be at least 40 decibels below the mean power of the fundamental without exceeding the power of 25 microwatts, but need not be reduced below the power of 10 microwatts.

(c) Paragraphs (a) and (b) of this section notwithstanding, all spurious emission or radiation from an amateur transmitter, transceiver, or external radio frequency power amplifier shall be reduced or eliminated in accordance with good engineering practice.

(d) If any spurious radiation, including chassis or power line radiation, causes harmful interference to the reception of another radio station, the licensee may be required to take steps to eliminate the interference in accordance with good engineering practice.

NOTE: For the purposes of this section, a spurious emission or radiation means any emission or radiation from a transmitter, transceiver, or external radio frequency power amplifier which is outside of the authorized Amateur Radio Service frequency band being used.

The numerical limits cited in 97.73 are interpreted graphically in Figs. 11 and 12. Note, however, that paragraphs (c) and (d) go beyond absolute limits in defining the amateur's obligation.

## Filters and Interference

The judicious use of filters, along with other suppression measures such as shielding, has provided solutions to interference problems in widely varying applications. As a consequence, considerable attention has been given to the subject over the years resulting in some very esoteric designs. Perhaps the most modern approach is to design filters with a digital computer. However, there are a number of other types with component values presented in tabular form. Of these, the most important ones are the so-called Chebyshev and elliptic-function filters. (Butterworth filters are often considered a special case of Chebyshev types with a ripple factor of zero.)

Elliptic-function filters might be considered optimum in the sense that they provide the sharpest rolloff between the passband and stopband. Computed values for a low-pass filter with a 0.1-dB ripple in the passband and a cutoff frequency of 30.6

MHz are shown in Fig. 13. The filter is supposed to provide an attenuation of 35 dB above 40 MHz. An experimental model was built and the response is shown in Fig. 14. As can be seen, the filter came close to the design goals. Unfortunately, as with most of the designs in this section, alignment of the more complicated filters requires some sort of sweep-generator setup. This is the only practical way of tweaking a filter to the desired response. While building a sweep setup is not beyond the talents of an advanced experimenter, the lack of one is not an obstacle in the home construction of filters.

## AN ABSORPTIVE FILTER

The filter shown in Fig. 15 not only provides rejection by means of a low-pass section, it also includes circuitry that absorbs harmonic energy. A high-pass section consisting of L1, L2, C1 and C2 is terminated in a 50-ohm idler load. This combination absorbs harmonics. The advantages of this technique are that degradation of filter rejection caused by antenna mismatch at the harmonic frequency is not as severe, and the transmitter is terminated in a resistive load at the harmonic.

### Construction and Test Techniques

If good performance above 100 MHz is not a necessity, this filter can be built using conventional fixed capacitors. Teflon® - dielectric PC board can be purchased from Microwave Components of Michigan, listed in Chapter 35. Regular fiberglass-insulated board is satisfactory for low power. One such filter has been used with an SSB transceiver running 100 watts PEP output. Although the Q of the fiberglass capacitors will be lower than that of Teflon® - dielectric capacitors, this should not greatly affect the type of filter described here.

Test equipment needed to build this filter at home includes a reasonably accurate dip oscillator, an SWR bridge, a reactance chart or the ARRL L/C/F Calculator, a 50-ohm dummy load and a transmitter.

Once the value of a given capacitor has been calculated, the next step is to determine the capacitance per square inch of the double-clad circuit board you have. This is done by connecting one end of a coil of known inductance to one side of the circuit board, and the other coil lead to the other side of the circuit board. Use a dip meter, coupled lightly to the coil, to determine the resonant frequency of the coil and the circuit-board capacitor. When the frequency is known, the total capacitance can be determined by working the calculator or by looking the capacitance up on a reactance chart. The total capacitance divided by the number of square inches on one side of the circuit board gives the capacitance per square inch. Once this figure is determined, capacitors of almost any value can be laid out with a ruler!

High voltages can be developed across capacitors in a series-tuned circuit, so the

Fig. 14 — Response curve of the filter shown in Fig. 13. Vertical scale represents 10 dB/div, and horizontal scale is 10 MHz/div.

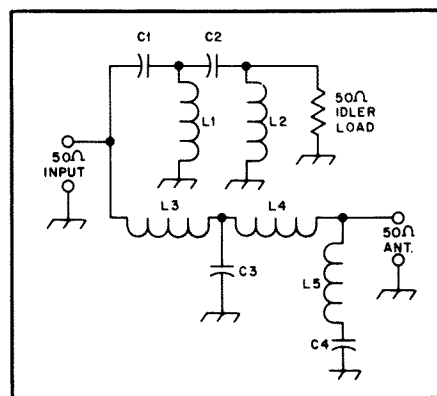

Fig. 15 — Schematic diagram of the absorptive filter. The pc-board used is MIL-P-13949D, FL-GT-062 in, C-2/2-11017, Class 1, Grade A. Polychem Bud Division. Capacitance between copper surfaces is 10-pF per square inch. Values are as follows for a design cutoff frequency of 40 MHz and rejection peak in TV channel 2:

C1 — 52 pF	L2 — 0.52 μH
C2 — 73 pF	L3 — 0.3 μH
C3 — 126 pF	L4 — 0.212 μH
C4 — 15 pF	L5 — 0.55 μH
L1 — 0.125 μH	

copper material should be trimmed back at least 1/8 inch from all edges of a board, except those that will be soldered to ground, to prevent arcing. This should not be accomplished by filing, because the copper filings would become imbedded in the board material and just compound the problem. The capacitor surfaces should be kept smooth, and sharp corners should be avoided.

If the filter box is made of double-clad fiberglass board, both sides should be bonded together with copper stripped from another piece of board. Stripped copper foil may be cleaned with a razor blade before soldering. To remove copper foil from a board, use a straight edge and a sharp scribe to score the thin copper foil. When the copper foil has been cut, use a razor blade to lift a corner. This technique of bonding two pieces of board can also be used to interconnect two capacitors when construction in one plane would require too

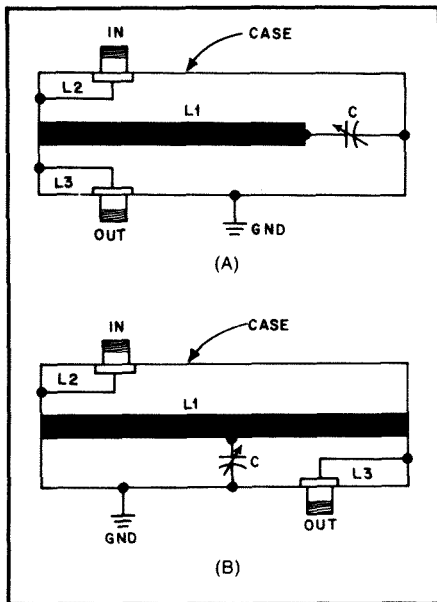

Fig. 16 — Equivalent circuits for the strip-line filters. At A, the circuit for the 6- and 2-meter filters are shown. L2 and L3 are the input and output links. These filters are bilateral, permitting interchanging of the input and output terminals. At B, the representative circuit for the 220- and 432-MHz filters. These filters are also bilateral.

much area. Stray inductance must be minimized and sufficient clearance must be maintained for arc-over protection.

Capacitors with Teflon® dielectric have been used in filters passing up to 2 kW PEP. One further word of caution: No low-pass filter will be fully effective until the transmitter with which it is used is properly shielded and all leads filtered.

The terminating loads for the high-pass section of the filter can be made from 2-watt, 10-percent-tolerance composition resistors. Almost any dissipation rating can be obtained by suitable series-parallel combinations. A 16-watt, 50-ohm load should handle the harmonic energy of a signal with peak fundamental power of 2 kilowatts. With this load, the harmonic energy will see an SWR of less than 2:1 up to 400 MHz. For low power (<300 watts PEP), a pair of 2-watt, 100-ohm resistors is adequate.

This filter was originally described by Weinrich and Carroll in November 1968 *QST*. The component values given here were calculated by Keith Wilkinson, ZL2BJR.

### VHF TVI CAUSES AND CURES

The principal causes of TVI from VHF transmitters are:

- 1) Interference in channels 2 and 3 from 50 MHz.
- 2) Fourth harmonic of 50 MHz in channels 11, 12 or 13, depending on the operating frequency.
- 3) Radiation of unused harmonics of the oscillator or multiplier stages. Examples are 9th harmonic of 6 MHz, and 7th harmonic

of 8 MHz in channel 2; 10th harmonic of 8 MHz in channel 6; 7th harmonic of 25-MHz stages in channel 7; 4th harmonic of 48-MHz stages in channel 9 or 10; and many other combinations. This may include IF pickup, as in the cases of 24-MHz interference in receivers having 21-MHz IF systems, and 48-MHz trouble in 45-MHz IFs.

4) Fundamental blocking effects, including modulation bars, usually found only in the lower channels, from 50-MHz equipment.

5) Image interference in channel 2 from 144 MHz, in receivers having a 45-MHz IF.

6) Sound interference (picture clear in some cases) resulting from RF pickup by the audio circuits of the TV receiver.

There are other possibilities, but nearly all can be corrected completely. The rest can be substantially reduced.

Items 1, 4 and 5 are receiver faults, and no amount of filtering at the transmitter can eliminate them. The only cure is to reduce the amount of 50-MHz energy reaching the receiver, such as by reducing power. In mild cases, increasing the separation between the transmitting and TV antenna systems may reduce or eliminate the problem. Item 6 is also a receiver fault, but it can be alleviated at the transmitter by using FM or CW instead of SSB.

Treatment of the various harmonic troubles, Items 2 and 3, follows the standard methods detailed elsewhere in this Handbook. The prospective builder of new VHF equipment should become familiar with TVI prevention techniques and incorporate them in new construction projects.

Use as high a starting frequency as possible to reduce the number of harmonics that might cause trouble. Select crystal frequencies that do not have harmonics in local TV channels. Example: The 10th harmonic of 8-MHz crystals used for operation in the low part of the 50-MHz band falls in channel 6, but 6-MHz crystals for the same band have no harmonic in that channel.

If TVI is a serious problem, use the lowest transmitter power that will do the job at hand. Keep the power in the multiplier and driver stages at the lowest practical level, and use link coupling in preference to capacitive coupling. Plan for complete shielding and filtering of the RF sections of the transmitter, should these steps become necessary.

Use coaxial line to feed the antenna system, and locate the radiating portion of the antenna as far as possible from TV receivers and their antenna systems.

A complete discussion of the problems and cures for interference is in the ARRL publication, *Radio Frequency Interference*.

### FILTERS FOR VHF TRANSMITTERS

High rejection of unwanted frequencies is possible with the tuned-line filters of Fig. 16. Examples are shown for each band from 50 through 450 MHz. Construction is relatively simple, and the cost is low.

Fig. 17 — Interior of the 50-MHz strip-line filter. Inner conductor of aluminum strip is bent into U shape, to fit inside a standard 17-inch chassis.

Fig. 18 — The 144-MHz filter has an inner conductor of 1/2-inch (5/8-inch OD) copper tubing 10 inches long, grounded to the left end of the case and supported at the right end by the tuning capacitor.

Fig. 19 — A half-wave strip line is used in the 220-MHz filter. It is grounded at both ends and tuned at the center.

Standard boxes are used for ease of duplication.

The filter of Fig. 17 is selective enough to pass 50-MHz energy and attenuate the seventh harmonic of an 8-MHz oscillator that falls in TV channel 2. With an insertion loss at 50 MHz of about 1 dB, it can provide up to 40 dB of attenuation to energy at 57 MHz in the same line.

The filter uses a folded line in order to keep it within the confines of a standard chassis. The case is a 6 × 17 × 3-inch chassis (Bud AC-433) with a cover plate that fastens in place with self-tapping screws. An aluminum partition down the middle of the assembly is 14 inches long, and the full height of the chassis is 3 inches.

The inner conductor of the line is 32 inches long and 13/16-inch wide, of 1/16-inch brass, copper or aluminum. This was made from two pieces of aluminum spliced together to provide the 32-inch length. Splicing seemed to have no ill effect on the circuit Q. The sides of the "U" are 2-7/8 inches apart, with the partition at the center. The line is supported on ceramic standoffs. These were shimmed with sections of hardwood or Bakelite rod, to give the required 1 1/2-inch height.

The tuning capacitor is a double-spaced variable (Hammarlund HF-30-X) mounted 1½ inches from the right end of the chassis. Input and output coupling loops are of no. 10 or 12 wire, 10 inches long. Spacing from the line is adjusted to about ¼ inch.

The 144-MHz model shown in Fig. 18 is housed in a 2¼ × 2½ × 12-inch Minibox® (Bud CU-2114-A).

One end of the tubing is slotted ¼-inch deep with a hacksaw. This slot takes a brass angle bracket 1½ inches wide, ¼ inch high, with a ½-inch mounting lip. The ¼-inch lip is soldered into the tubing slot, and the bracket is then bolted to the end of the box, so as to be centered on the end plate.

The tuning capacitor (Hammarlund HF-15-X) is mounted 1¼ inches from the other end of the box, in such a position that the inner conductor can be soldered to the two stator bars.

The two coaxial fittings (SO-239) are 11/16 inch in from each side of the box, 3½ inches from the left end. The coupling loops are no. 12 wire, bent so that each is parallel to the center line of the inner conductor, and about 1/8 inch from its surface. Their cold ends are soldered to the brass mounting bracket.

The 220-MHz filter (Fig. 19) uses the same size box as the 144-MHz model. The inner conductor is 1/16-inch brass or copper, 5/8-inch wide, just long enough to fold over at each end for bolting to the box. It is positioned so that there will be a 1/8-inch clearance between it and the rotor plates of the tuning capacitor. The latter is a Hammarlund HF-15-X, mounted slightly off-center in the box, so that its stator plates connect to the exact mid-point of the line. The 5/16-inch mounting hole in the case is 5½ inches from one end. The SO-239 coaxial fittings are 1 inch in from opposite sides of the box, 2 inches from the ends. Their coupling links are no. 14 wire, 1/8 inch from the inner conductor of the line.

The 420-MHz filter is similar in design, using a 1-5/8 × 2 × 10-inch Minibox (Bud CT-2113-A). A half-wave line is used, with the disc tuning at the center. The discs are 1/16-inch brass, 1¼-inch diameter. The fixed one is centered on the inner conductor, the other is mounted on a no. 6 brass lead-screw. This passes through a threaded bushing, which can be taken from the end of a discarded slug-tuned form. An advantage of these is that usually a tension device is included. If there is none, use a lock nut.

Type-N coaxial connectors were used on the 420-MHz model. They are 5/8 inch in from each side of the box, and 1-3/8 inches in from the ends. Their coupling links of no. 14 wire are 1/16 inch from the inner conductor.

#### Adjustment and Use

If you want the filter to work on both transmitting and receiving, connect the filter between antenna line and SWR in-

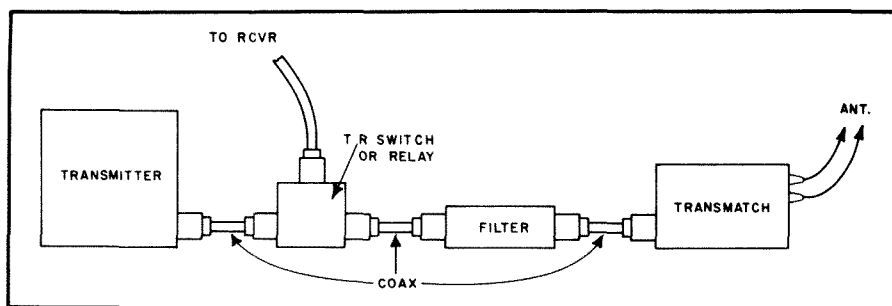

Fig. 20 — The proper method of installing a low-pass filter between the transmitter and a Transmatch. If the antenna is fed through coax, the Transmatch can be eliminated, but the transmitter and filter must be completely shielded. If a TR switch is used, it should be installed between the transmitter and low-pass filter. TR switches can generate harmonics themselves, so the low-pass filter should follow the TR switch.

dicator. With this arrangement you need merely adjust the filter for minimum reflected power reading on the SWR bridge. This should be zero, or close to it, if the antenna is well matched. The bridge should be used, as there is no way to adjust the filter properly without it.

When the filter is properly adjusted (with the SWR bridge), you may find that reception can be improved by retuning the filter. Don't do it if you want the filter to work best for the job it was intended to do: The rejection of unwanted energy, transmitting or receiving. If you want to improve reception with the filter in the circuit, work on the receiver input circuit. To get maximum power out of the transmitter and into the line, adjust the transmitter output coupling, not the filter. If the effect of the filter on reception bothers you, connect it in the line from the antenna relay to the transmitter only.

#### Summary

The methods of harmonic elimination outlined here have been proven beyond doubt to be effective even under highly unfavorable conditions. It must be emphasized once more, however, that the problem must be solved one step at a time, and the procedure must be in logical order. It cannot be done properly without two items of simple equipment: A dip meter and wavemeter covering the TV bands, and a dummy antenna.

To summarize:

- 1) Take a critical look at the transmitter on the basis of the design considerations outlined under Reducing Harmonic Generation.

- 2) Check all circuits, particularly those connected with the final amplifier, with the dip meter to determine whether there are any resonances in the TV bands. If so, rearrange the circuits so the resonances are moved out of the critical frequency region.

- 3) Connect the transmitter to the dummy antenna and check for the presence of harmonics on leads with the wavemeter and around the transmitter enclosure. Seal the weak spots in the shielding and filter the leads until the wavemeter shows no indication at any harmonic frequency.

- 4) At this stage, check for interference with a TV receiver. If there is interference, determine the cause by the methods described previously and apply the recommended remedies until the interference disappears. More than one remedy may be required.

- 5) When the transmitter is completely clean on the dummy antenna, connect it to the regular antenna and check for interference on the TV receiver. If the interference is not bad, a Transmatch or matching circuit, installed as shown in Fig. 20, should clear it up. Alternatively, a low-pass filter may be used. If neither the Transmatch nor filter makes any difference in the interference, the evidence is strong that the interference, at least in part, is being caused by receiver overloading because of the strong fundamental-frequency field about the TV antenna and receiver. A Transmatch and/or filter, installed as described above, will invariably make a difference if the interference is caused by transmitter harmonics alone.

- 6) If there is still interference after installing the Transmatch and/or filter, and the evidence shows that it is probably caused by a harmonic, more attenuation is needed. A more elaborate filter may be necessary. However, it is well at this stage to assume that part of the interference may be caused by receiver overloading. Take steps to alleviate such a condition before trying highly elaborate filters and traps on the transmitter.

#### Harmonics by Rectification

Even though the transmitter is completely free of harmonic output, it is still possible for interference to occur because of harmonics generated outside the transmitter. These result from rectification of fundamental-frequency currents induced in conductors in the vicinity of the transmitting antenna. Rectification can take place at any point where two conductors are in poor electrical contact, a condition that frequently exists in plumbing, downspouting, BX cables crossing each other, and numerous other places in an ordinary residence. It can also occur at any exposed circuitry in the station that may not be shielded from RF. Poor joints anywhere in

Fig. 21 — The schematic diagram of a 75-ohm Chebyshev filter assembled on PC board is shown at A. At B, the passband response of the 75-ohm filter. Design inductances: 0.157  $\mu$ H: 12 turns no. 24 wire on T44-0 core. 0.135  $\mu$ H: 11 turns no. 24 wire on T44-0 core. Turns should be evenly spaced, with approximately  $\frac{1}{4}$  inch between the ends of the winding. If T37-0 cores are used, wind 14 and 12 turns, respectively.

Fig. 22 — Photo showing construction of the 75-ohm unbalanced filter.

the antenna system are especially bad, and rectification may take place in the contacts of antenna-changeover relays. Another rectification problem is caused by overloading the front end of the communications receiver when it is used with a separate antenna. This can result in the radiation of harmonics generated in the first stage of the receiver.

Rectification of this sort will not only cause harmonic interference, but also is frequently responsible for cross-modulation effects. It can be detected to some degree in most locations, but fortunately the harmonics thus generated are not usually of high amplitude. However, they can cause considerable interference in the immediate vicinity in fringe areas, especially when operation is in the 28-MHz band. The amplitude decreases rapidly with the order of the harmonic, the second and third being the worst. It is ordinarily found that even in cases where destructive interference results from 28-MHz operation, the interference is comparatively mild from 14 MHz, and is negligible at still lower frequencies.

Nothing can be done at either the transmitter or receiver when rectification occurs in other objects. The remedy is to find and eliminate the poor contact either by separating the conductors or bonding them together. A crystal wavemeter (tuned to the fundamental frequency) is useful for hunting the source by showing which conductors are carrying RF and, comparatively, how much.

Interference of this kind is frequently intermittent since the rectification efficiency will vary with its susceptibility to vibration, weather and so on. The possibility of cor-

roded contacts in the TV receiving antenna should not be overlooked, especially if it has been up for a year or more.

### TV Receiver Deficiencies

When a television receiver is located close to the transmitter, the intense RF signal from the transmitter's fundamental may overload one or more of the receiver circuits to produce spurious responses that cause interference.

If the overload is moderate, the interference is of the same nature as harmonic interference; it is caused by harmonics generated in the early stages of the receiver and, since it occurs only on channels harmonically related to the transmitting frequency, it is difficult to distinguish from harmonics actually radiated by the transmitter. In such cases, additional harmonic suppression at the transmitter will do no good, but any means taken at the receiver to reduce the strength of the amateur signal reaching the first stage will improve performance. With very severe overloading, interference also will occur on channels not harmonically related to the transmitting frequency, so such cases are easily identified.

### Intermodulation

Under some circumstances, overloading will result in cross modulation or mixing of the amateur signal with that from a local FM or television station. For example, a 14-MHz signal can mix with a 92-MHz FM station to produce a beat at 78 MHz, the difference between the two frequencies ( $92 - 14 = 78$ ). Since 78 MHz falls in TV channel 5, interference to television recep-

tion would occur on that channel. Similarly, a 14-MHz signal could mix with a TV broadcast station operating on channel 6 to produce a beat at 99 MHz, the sum of the two frequencies ( $14 + 85 = 99$ ). Neither of the broadcast channels interfered with is in harmonic relationship to 14 MHz, and both signals must be on the air for the interference to occur. Eliminating either at the receiver will eliminate the interference.

There are many combinations of this type, depending on the band in use and the local frequency assignments of FM and TV stations. As noted earlier, the interfering frequency is equal to the amateur fundamental frequency either added to, or subtracted from, the frequency of some local station. Whenever interference occurs in a frequency that is not harmonically related to the amateur transmitter frequency, the possibilities in such frequency combinations should be investigated.

### IF Interference

Some TV receivers do not have sufficient selectivity to prevent strong signals in the intermediate-frequency range from forcing their way through the front end and getting into the IF amplifier. The third harmonic of 14 MHz and second harmonic of 21 MHz fall into the television IF, as do some of the local-oscillator frequencies used in a heterodyne type of transmitter or transceiver. If these frequencies are breaking through the TV tuner, a high-pass filter can improve the situation significantly. Even so, the amateur is responsible for keeping his or her radiation in the TV IF region within the limits defined by FCC rules and

Fig. 23 — Schematic and pictorial diagrams of the 300-ohm balanced elliptical high-pass filter with PC-board capacitors. Shaded areas indicate where copper has been removed. Dimensions are given in millimeters for ease of measurement. L2-C2 connects between the points marked x, L4-C4 connects between the points marked y and L6-C6 connects between the points marked z on the pictorial. C1 = 28.0 pF, C3 = 14.0 pF, C5 = 14.8 pF, C7 = 34.2 pF, C2 = 162 pF, C4 = 36.0 pF, and C6 = 46.5 pF. Design inductances: L2 = 0.721  $\mu$ H: 14 turns no. 26 wire evenly wound on a T44-10 core. L4 = 0.766  $\mu$ H: 14 turns no. 26 wire bunched as required on a T44-10 core. L6 = 0.855  $\mu$ H: 15 turns evenly wound on a T44-10 core. These coils should be adjusted for resonance at 14.7, 30.3 and 25.2 MHz.

good engineering practice.

A form of IF interference peculiar to 50-MHz operation near the low edge of the band occurs with some receivers having the standard 41-MHz IF, which has the sound carrier at 41.25 MHz and the picture carrier at 45.75 MHz. A 50-MHz signal that forces its way into the IF system of the receiver will beat with the IF picture carrier to give a spurious signal on or near the IF sound carrier, even though the interfering signal is not actually in the normal passband of the IF amplifier.

There is a type of IF interference unique to the 144-MHz band in localities where certain UHF TV channels are in operation. It affects only those TV receivers in which double-conversion type plug-in UHF tuning strips are used. The design of these strips involves a first intermediate frequency that varies with the TV channel to be received and, depending on the particular strip design, this first IF may be in or close to the 144-MHz amateur band. Since there is comparatively little selectivity in the TV

signal-frequency circuits ahead of the first IF, a signal from a 144-MHz transmitter will ride into the IF, even when the receiver is at a considerable distance from the transmitter. The channels that can be affected by this type of IF interference are 20-25, 51-58, 82 and 83. If the receiver is not close to the transmitter, a trap of the type shown in Fig. 25 will be effective. However, if the separation is small, the 144-MHz signal will be picked up directly on the receiver circuits. The best solution is to readjust the strip oscillator so that the first IF is moved to a frequency not in the vicinity of the 144-MHz band. This should be done only by a competent technician.

IF interference is easily identified since it occurs on all channels — although sometimes the intensity varies from channel to channel — and the cross-hatch pattern it causes will rotate when the receiver's fine-tuning control is varied. When the interference is caused by a harmonic, overloading or cross modulation, the structure of the interference pattern does not change

(its intensity may change) as the fine-tuning control is varied.

### High-Pass Filters

In all of these cases the interference can be eliminated if the fundamental signal strength is reduced to a level that the receiver can handle. To accomplish this with signals on bands below 30 MHz, the most satisfactory device is a high-pass filter having a cutoff frequency just below 54 MHz installed at the tuner input terminals of the receiver.

Fig. 21 shows the schematic diagram of a filter designed for use with 75-ohm coaxial cable. Double-sided 1/16-inch FR-4 epoxy-glass PC board is used as a base for the filter components. A section of copper on the top is stripped away on both sides of center to approximate a 75-ohm microstrip line about 3/32-inch wide (see Fig. 21). Both sides of the top copper foil (at the edges) are connected to the ground plane foil underneath.

Slice off the extruded insulation around

(B)

Fig. 24 — A top view of the 300-ohm elliptical filter using PC-board capacitors is at A. Twin-lead is tack soldered at the left and right ends of the board. At B, bottom view of the filter.

Fig. 25 — Parallel-tuned traps for installation in the 300-ohm line to the TV set. The traps should be mounted in an aluminum Minibox with a shield partition between them, as shown. For 50 MHz, the coils should have nine turns of no. 16 enamel wire, close-wound to a diameter of  $\frac{1}{2}$  inch. The 144-MHz traps should contain coils with a total of six turns of the same type wire close-wound to a diameter of  $\frac{1}{4}$  inch. Traps of this type can be used to combat fundamental-overload TVI on the lower-frequency bands as well.

the solder pins on two type-F coaxial connectors (Radio Shack 278-212). Butt the connectors directly against the PC board. Solder the connector shells to the bottom ground plane and the center pins to the micro-strip line. Cut the micro-strip line in four equally spaced places. The capacitors should be mounted across the spaces; inductors can be connected between the capacitor junctions and the ground plane on the top of the board. Use NP0 ceramic or silver mica capacitors. Inductors are wound on toroidal powdered-iron cores; winding details are given in Fig. 22.

Fig. 22 shows the schematic and pictorial diagrams of a 300-ohm balanced elliptical high-pass filter that uses PC-board capacitors. Use double-sided  $1/32$  inch FR-4 glass-epoxy PC board. Thicker board will require more area for the desired capacitances. C2, C4 and C6 should be NP0 ceramic or silver-mica capacitors. It is easier to strip away rather than etch copper to form the series of capacitive elements. Mark the edges by cutting with a sharp knife; heating with a hot soldering iron will help lift the strips more easily. Top and bottom views of the filter are shown in Fig. 24.

Neither of the high-pass filters described requires a shielded enclosure. For mounting outside the receiver, some kind of protective housing is desirable, however. These filters were presented in "Practical 75- and 300-Ohm High-Pass Filters," *QST*, February 1982, by Ed Wetherhold, W3NQK.

Simple high-pass filters cannot always be applied successfully in the case of 50-MHz transmissions, because they do not have sufficiently sharp cutoff characteristics to give both good attenuation at 50-54 MHz and no attenuation above 54 MHz. A more elaborate design capable of giving the required sharp cutoff has been described (Ladd, "50-MHz TVI — Its Causes and Cures," *QST*, June and July 1954). This article also contains other information

useful in coping with the TVI problems peculiar to 50-MHz operation.

As an alternative to such a filter, a high-Q wave trap tuned to the transmitting frequency may be used, suffering only the disadvantage that it is quite selective and therefore will protect a receiver from overloading over only a small range of transmitting frequencies in the 50-MHz band. A trap of this type is shown in Fig. 25. These suck-out traps, while absorbing energy at the frequency to which they are tuned, do not affect the receiver operation otherwise. The assembly should be mounted near the input terminals of the TV tuner and its case should be RF grounded to the TV set chassis by means of a small capacitor. The traps should be tuned for minimum TVI at the transmitter operating frequency. An insulated tuning tool should be used for adjustment of the trimmer capacitors, since they are at a hot point and will show considerable body-capacitance effect.

High-pass filters are available commercially at moderate prices. In this connection, it should be understood by all parties concerned that while an amateur is responsible for *harmonic* radiation from his transmitter, it is no part of his responsibility to pay for or install filters, wave traps or other devices that may be required at the receiver to prevent interference caused by his *fundamental* frequency. Proper installation usually requires that the filter be installed at the input terminals of the RF tuner of the TV set and not merely at the external antenna terminals, which may be at a considerable distance from the tuner. The question of cost is one to be settled between the set owner and the organization with which he deals. Don't overlook the possibility that the manufacturer of the TV receiver may supply a high-pass filter free of charge.

If the fundamental signal is getting into the receiver by way of the line cord, a line filter such as those shown in Fig. 26 may help. To be most effective it should be installed inside the receiver chassis at the point where the cord enters, making the ground connections directly to the chassis at this point. It may not be so helpful if placed between the line plug and the wall socket unless the RF is actually picked up on the house wiring rather than on the line cord itself.

#### Antenna Installation

Usually the transmission line between the TV receiver and the antenna will pick up a great deal more energy from a nearby HF transmitter than the television receiving antenna itself. The currents induced on the TV transmission line in this case are of the parallel type, where the phase of the current is the same in both conductors. The line simply acts like two wires connected together to operate as one. If the receiver antenna input circuit were perfectly balanced it would reject these parallel or common-mode signals and respond only to the true transmission-line (push-pull or dif-

Fig. 26 — Brute-force ac line filter for receivers. The values of C1, C2 and C3 are not generally critical; capacitances from 0.001 to 0.01  $\mu$ F can be used. L1 and L2 can be a 2-inch winding of no. 18 enameled wire on a  $\frac{1}{2}$ -inch-diameter form. In making up such a unit for use external to the receiver, make sure there are no exposed conductors to offer a shock hazard.

ferential mode) currents. That is, only signals picked up on the actual antenna would cause a receiver response. However, no receiver is perfect in this respect, and many TV receivers will respond strongly to such common-mode currents. The result is that the signals from a nearby amateur transmitter are much more intense at the first stage in the TV receiver than they would be if the receiver response were confined entirely to energy picked up on the TV antenna alone.

A simple common-mode choke can be formed by winding several turns of TV twin-lead through an FT-114 ferrite core. Best results will be obtained if you use twin-lead with an oval cross-sectional profile.

The situation can also be improved by using coaxial cable or shielded twin-lead. For best results, coax line should terminate in a coaxial fitting on the receiver chassis. A balun can be used between the coax and the 300-ohm balanced input terminals of a receiver having no coaxial connector. The foil of shielded twin-lead should be connected to the chassis near the antenna terminals through a small capacitor (470 pF). RF currents on the outside of the shield can be dealt with effectively by using a shield choke as described earlier in this chapter.

In most TV receiving installations the transmission line is much longer than the antenna itself, and is consequently exposed to more of the harmonic fields from the transmitter. Much of the harmonic pickup, therefore, is on the receiving transmission line when the transmitter and receiver are located close together. Shielded line, plus relocation of either the transmitting or receiving antenna to take advantage of directive effects, often will reduce overloading and harmonic pickup to a level that does not interfere with reception.

#### UHF Television

Harmonic TVI in the UHF-TV band is far less troublesome than in the VHF band. Harmonics from transmitters operating below 30 MHz are of such high order that they would normally be expected to be weak; in addition, the components, circuit conditions and construction of low-

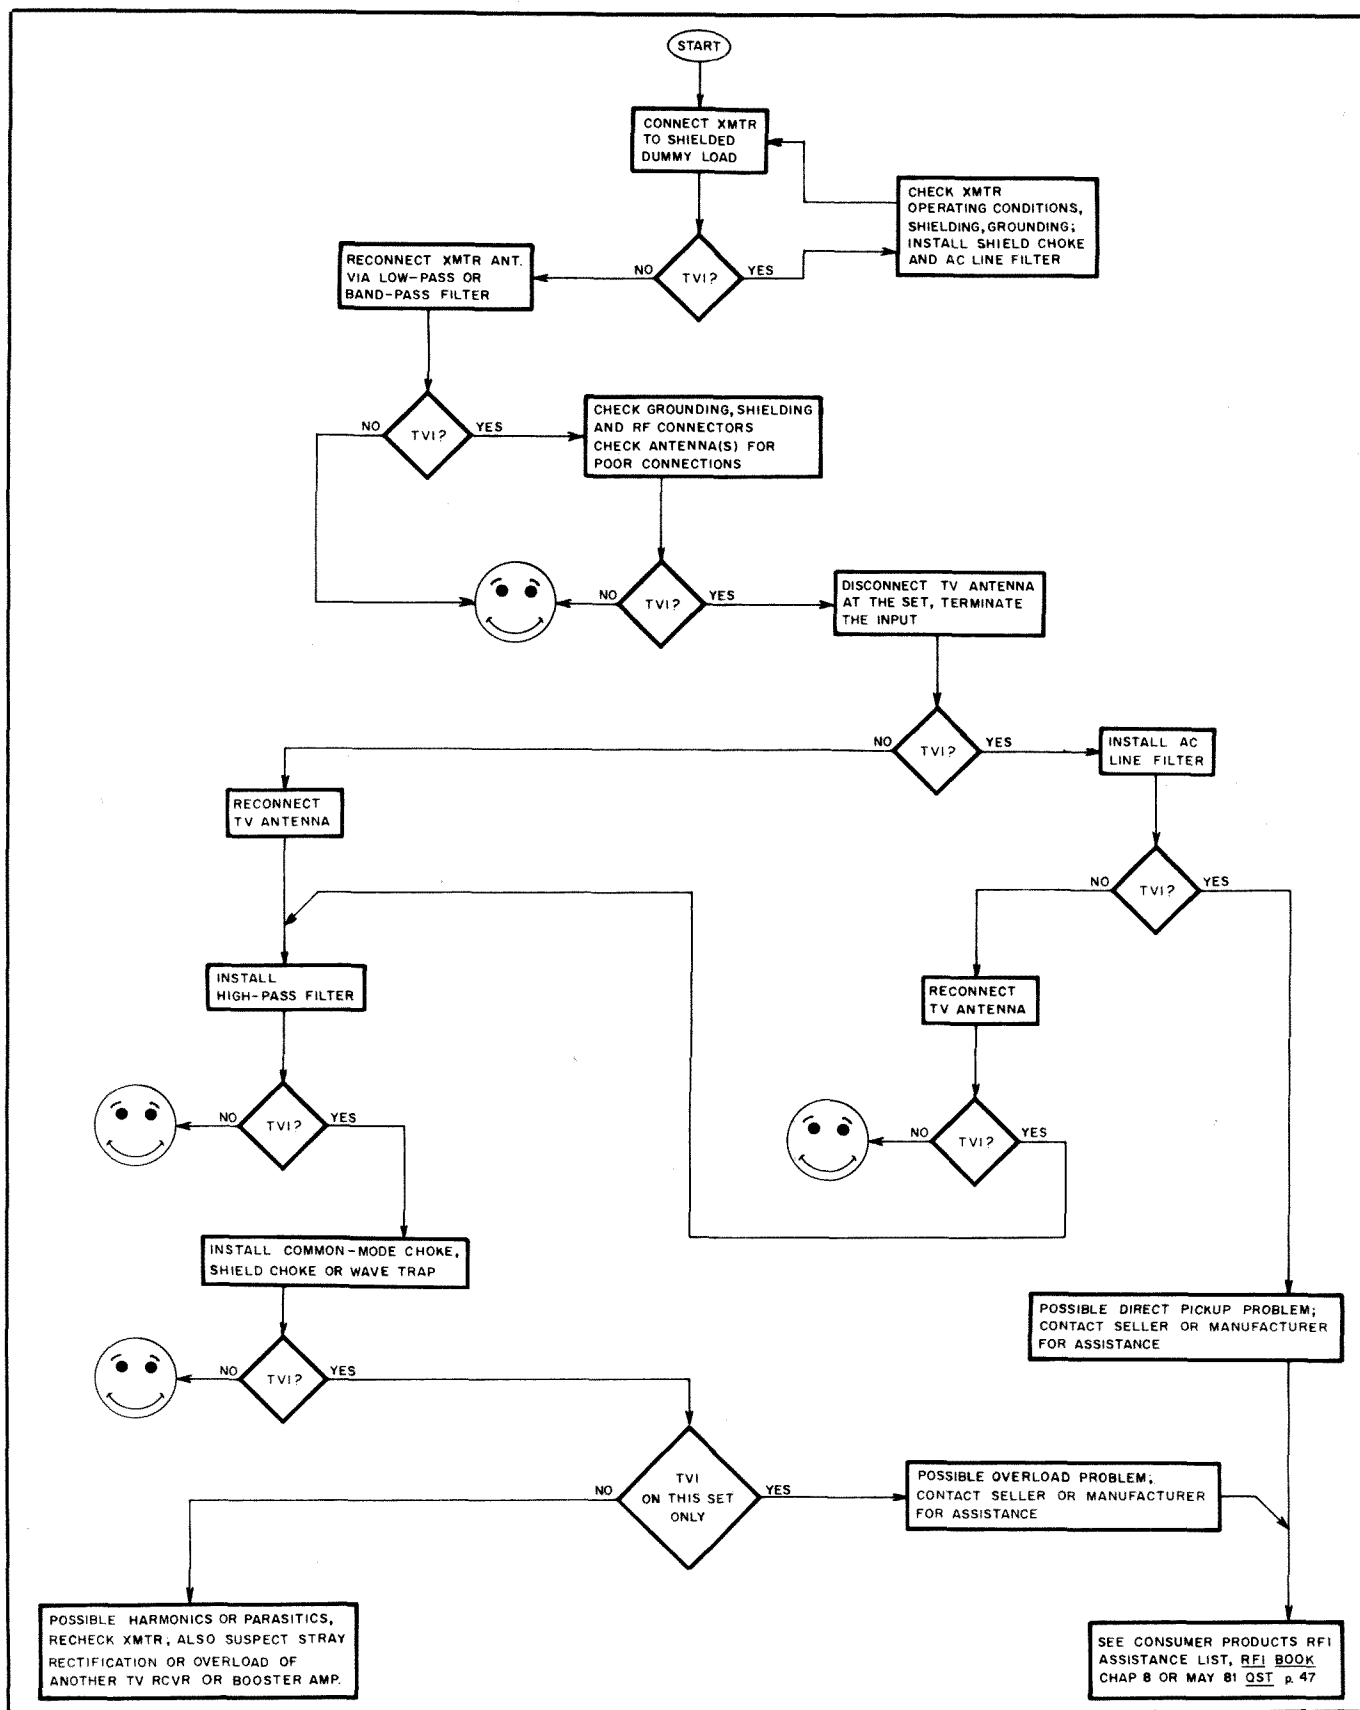

Fig. 27 — TVI troubleshooting flowchart.

frequency transmitters tend to prevent very strong harmonics from being generated in this region. However, this is not true of amateur VHF transmitters, particularly

those working in the 144-MHz and higher bands. Here the problem is similar to that of the low VHF-TV band with respect to transmitters operating below 30 MHz.

There is one highly favorable factor in UHF TV that does not exist in most of the VHF-TV band: If harmonics are radiated, it is possible to move the transmitter fre-

**Table 1**  
**Harmonic Relationship — Amateur VHF Bands and the UHF TV Channels**

Amateur Band	Harmonic	Fundamental Freq. Range	Channel Affected
144 MHz	4th	144.0-144.5	31
		144.5-146.0	32
		146.0-147.5	33
		147.5-148.0	34
	5th	144.0-144.4	55
		144.4-145.6	56
		145.6-146.8	57
		146.8-148.0	58
	6th	144.0-144.33	79
		144.33-145.33	80
		145.33-146.33	81
		146.33-147.33	82
220 MHz	3rd	220-220.67	45
		220.67-222.67	46
		222.67-224.67	47
		224.67-225	48
	4th	220-221	82
		221-222.5	83

		421-424	76
		424-427	77
		427-430	78
		430-433	79
		433-436	80

quency sufficiently (within the amateur band being used) to avoid interfering with a channel that may be in use in the locality.

The harmonics from amateur bands above 50 MHz span the UHF channels as shown in Table 1. Since the assignment plan calls for a minimum separation of six channels between any two stations in one locality, there is ample opportunity to choose a fundamental frequency that will move a harmonic out of range of a local TV frequency.

### TVI Troubleshooting

Determination and experimentation are essential for success in tracking down and eliminating troublesome TVI. The variables involved are usually so complicated as to make the task more of an art than a science. To ensure a logical and systematic approach, use the TVI troubleshooting flowchart found in Fig. 27. The best place to begin is in your own home. Lessons learned there will assist you when dealing with problems elsewhere in the neighborhood.

### Stereo Interference

Since the introduction of stereo receivers, interference to this type of home-entertainment device has become a severe problem for amateurs. Unfortunately, most of the stereo equipment now being sold has little or no filtering to prevent RF interference. In most cases, corrective measures must be taken at the stereo installation.

### Stereo Equipment

Stereo gear can consist of a simple amplifier, with record or tape inputs and

Fig. 28 — A method for removing RF current from loudspeaker leads. The chokes should be near the output terminals, preferably within the amplifier cabinet. The RF chokes can be 24 turns of no. 18 wire closewound on a pencil.

speaker outputs. The more elaborate installations may also include a tape deck, turntable, AM/FM tuner, amplifier and two or more speakers. These units are usually connected by means of shielded leads, and in most cases the speakers are positioned some distance from the amplifier and connected with long leads. When such a setup is operated within a few hundred feet of an amateur station, there are two important paths through which RF energy can reach the stereo equipment and cause interference.

The first step is to try to determine how the interference is getting into the unit. If the volume control has no effect on the level of interference, or has a very slight effect, the audio rectification of the amateur signal is taking place past the volume control, or on the output end of the amplifier. This is by far the most common type. It usually means that the amateur signal is being picked up on the speaker leads, or possibly on the ac line, and is then being fed back into the amplifier.

Experience has shown that most of the RF gets into the audio system via the speaker leads, or the ac line, most often the speaker leads. If the speaker leads happen to be resonant near an amateur band in use, there is likely to be an interference problem. The speaker lead will act as a resonant antenna and pick up the RF. One easy cure is illustrated in Fig. 28. RF chokes rated to carry the load current are installed at the amplifier output terminals. Capacitors may be used on the *load* side of the chokes, but should not be placed on the amplifier side. Most solid-state audio amplifiers have high values of loop gain, which makes them prone to supersonic oscillation when working into capacitive loads. Such oscillation can destroy the output transistors in short order.

In particularly stubborn cases, use shielded wire for the speaker leads, grounding the shields at the amplifier chassis and still using the bypasses on the terminals. All chassis used in the stereo installation should be bonded together and connected to a good earth ground if at all possible. It has been found that grounding sometimes eliminates the interference. On the other hand, don't be discouraged if grounding doesn't appear to help.

Fig. 29 shows a method for filtering the

Fig. 29 — Ac line filter for audio amplifiers. The chokes are the same as those described in Fig. 28. The capacitors must be rated for ac service (or 1.4 kV dc).

ac line at the input of the amplifier chassis. Be sure that the capacitors are rated for ac because the dc types have been known to short out.

### Antenna Pickup

RF may also get into the audio equipment by way of the FM antenna, so precautions should be taken here. A TV-type high-pass filter can prove effective in some cases.

### Turntables and Tape Decks

In the more elaborate setups, several assemblies may be connected by means of patch cords. It is a good idea when checking for RFI to disconnect the units, one at a time, observing any changes in the interference. Not only disconnect the patch cords connecting the pieces, but also unplug the ac line cord for each item as you make the test. This will help you determine which section is the culprit.

Patch cords are usually, but not always, made of shielded cable. The lines should be shielded, which brings up another point. Many commercially available patch cords have poor shields. Some have wire spirally wrapped around the insulation, covering the main lead, rather than braid. This method provides poor shielding and could be the reason for RFI problems.

Record-player tone-arm connections to the cartridge are usually made with small clips. The existence of a loose clip, particularly if oxidation is present, offers an excellent invitation to RFI. Also, the leads from the cartridge and those to the amplifier are sometimes resonant at VHF, providing an excellent receiving antenna for RF. One cure for unwanted RF pickup is to install ferrite beads, one on each cartridge lead. Check all patch-cord connections for looseness or poor solder joints. Inferior connections can cause rectification and RFI.

Tape decks should be treated the same as turntables. Loose connections and bad solder joints can cause trouble. Ferrite beads can be slipped over the leads to the recording and play-back pickup heads. Bypassing of the tone-arm or pickup-head leads is also effective, but sometimes it is difficult to install capacitors in the small area available. Disc capacitors (0.001  $\mu$ F) should be used as close to the cartridge or

pickup head as possible. Keep the capacitor leads as short as possible.

### Preamplifiers

One or more preamplifiers are usually used in a stereo amplifier. The inputs to these stages can be very susceptible to RFI. Fig. 30 illustrates a typical preamplifier circuit. In this case the leads to the bases of the transistors are treated for RFI with ferrite beads by the addition of RFC2 and RFC4. This is a very effective method for stopping RFI when VHF energy is the source of the trouble.

The emitter-base junction of a transistor is a common RFI offender. This junction operates as a forward-biased diode, with the bias set so that a change of base current with signal will produce a linear but amplified change in collector current. Should RF energy reach the junction, the bias could increase, causing nonlinear amplification and distortion as the result. If the RF level is high it can completely block (saturate) a transistor, causing a complete loss of gain. Therefore, it may be necessary to reduce the transmitter power output to pinpoint the particular transistor stage that is affected.

In addition to ferrite beads placed over the base lead, it may be necessary to bypass the base of the transistor to chassis ground, C1 and C2, Fig. 30. A suitable value is 100 pF, and keep the leads short! As a rule, the capacitor value should be as large as possible without degrading the high-frequency response of the amplifier. Values up to 0.001  $\mu$ F can be used. In severe cases, a series inductor (RFC1 and RFC3) may be required, such as the Ohmite Z-50 or Z-144, or their equivalents (7 and 1.8  $\mu$ H, respectively). Fig. 30 shows the correct placement for an inductor, bypass capacitor and ferrite bead. Also, it might help to use a ferrite bead in the B+ lead to the preamplifier stages (RFC5 in Fig. 30). Keep in mind that Fig. 30 represents only one preamplifier of a stereo set. Both channels may require treatment.

### FM Tuners

Much of the interference to FM tuners is caused by fundamental overloading of the first stage (or stages). The cure is the installation of a high-pass filter, the same type used for TVI. The filter should be installed as close as possible to the antenna input of the tuner. The high-pass filter will attenuate the amateur fundamental signal, thus preventing overloading of the front end.

### Shielding

Lack of shielding on the various components in a stereo installation can permit RF to get into the equipment. Many units have no bottom plates, or are installed in plastic cases. One easy method of providing shielding is to use aluminum foil. Make sure the foil doesn't short-circuit the com-

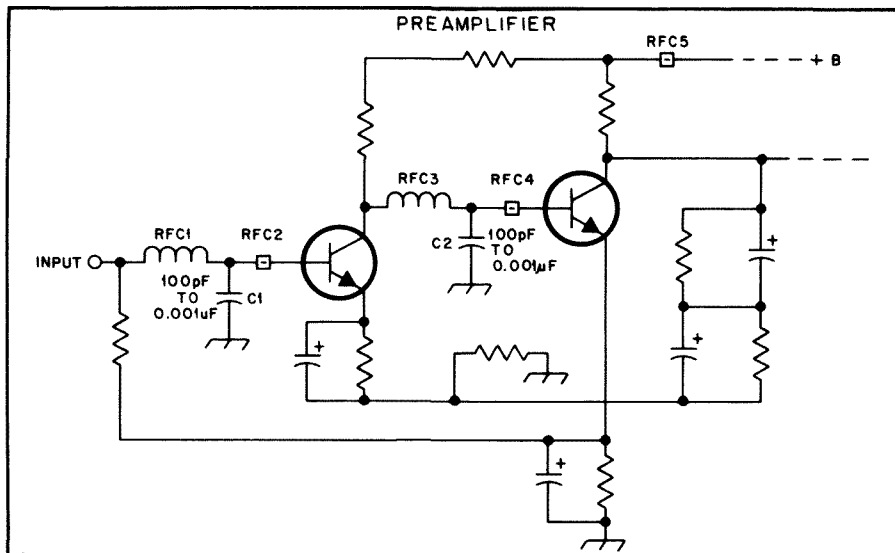

Fig. 30 — Typical circuit of a solid-state preamplifier.

ponents, and connect it to chassis ground.

### Interference with Medium-Wave Broadcast Reception

#### Transmitter Defects

Out-of-band radiation is something that must be cured at the amateur transmitter. Parasitic oscillations are a frequently unsuspected source of such radiation, and no transmitter can be considered satisfactory until it has been thoroughly checked for both low- and high-frequency parasitics. Very often, parasitics show up only as transients, causing key clicks in CW transmitters and "splashes" or "burps" on modulation peaks in SSB transmitters. Methods for detecting and eliminating parasitics are discussed in the transmitter chapter.

In CW transmitters the sharp make and break that occurs with unfiltered keying causes transients that, in theory, contain frequency components through the entire radio spectrum. Practically, they are often strong enough in the immediate vicinity of the transmitter to cause serious interference to broadcast reception. Key clicks can be eliminated by proper wave shaping. See Chapter 19.

BCI is frequently made worse by radiation from the power wiring or the RF transmission line. This is because the signal causing the interference is radiated from wiring that is nearer the broadcast receiver than the transmitting antenna. Much depends on the method used to couple the transmitter to the antenna, a subject that is discussed in the chapters on transmission lines and antennas. If at all possible, the antenna itself should be placed some distance from house wiring, telephone and power lines, and similar conductors.

#### The BC Receiver

Most present-day receivers use solid-state

active components rather than tubes. A large number of the receivers in use are battery powered. This is to the amateur's advantage because much of the BC interference an amateur encounters is caused by ac line pickup. In the case where the BC receiver is powered from the ac line, whether using tube or solid-state components, the amount of RF pickup must be reduced or eliminated. A line filter such as is shown in Fig. 26 often will help accomplish this. The values used for the coils and capacitors are in general not critical. The effectiveness of the filter may depend considerably on the ground connection used, and it is advisable to use a short ground lead to a cold-water pipe if at all possible. The line cord from the set should be bunched up to minimize the possibility of pickup on the cord. To get satisfactory operation, it may be necessary to install the filter inside the receiver, so the filter is connected between the line cord and the set wiring.

### Cross Modulation

With phone transmitters, there are occasionally cases where the noise is heard whenever the broadcast receiver is tuned to a BC station, but there is no interference when tuned between stations. This is cross modulation, a result of rectification in one of the early stages of the receiver. Receivers that are susceptible to this trouble usually also get a similar type of interference from regular broadcasting if there is a strong local BC station and the receiver is tuned to some other station.

The remedy for cross modulation in the receiver is the same as for images and oscillator-harmonic response — reduce the strength of the amateur signal at the receiver by means of a line filter.

The trouble is not always in the receiver. Cross modulation can occur in any nearby

rectifying circuit — such as a poor contact in water or gutter pipes, and other conductors in the strong field of the transmitting antenna. Locating the cause may be difficult, and is best attempted with a battery-powered portable broadcast receiver used as a probe to find the spot where the interference is most intense. When such a spot is located, inspection of the metal structures in the vicinity should indicate the cause. The remedy is to make a good electrical bond between the two conductors having the poor contact.

#### **Handling BCI Cases**

Tune the receiver through the broadcast band to see whether the interference tunes like a regular BC station. If so, image or oscillator-harmonic response is the cause. If there is interference only when a BC station is tuned in, but not between stations, the cause is cross modulation. If the interference is heard at all settings of the tuning dial, the trouble is pickup in the audio circuits. In this case, the receiver volume control may or may not affect the strength of the interference, depending on how your signal is being rectified.

#### **Organs**

The electronic organ is an RFI problem area. All of the techniques outlined for audio gear hold true in getting rid of RFI in an organ. Two points should be checked — the speaker leads and the ac line. Many organ manufacturers have special service guides for taking care of RFI. However, to get this information you or the organ owner must contact the manufacturer, not the dealer or distributor. Don't accept the statement from a dealer or serviceman that nothing can be done about the interference.

#### **Public Address Systems**

The cure for RFI in public address systems is almost the same as that for audio gear. The one thing to watch for is RF on the leads that connect the various stations

in a public address system. These leads should be treated the same as speaker leads, and filtering should be done at both ends of the lines. Also, watch for ac-line pickup of RF.

#### **Telephone Interference**

Because of a change in FCC rules, subscribers increasingly own their telephone instruments, leasing only the lines from the telephone company. Interference-prevention measures to the instrument are the owner's responsibility. If a fault occurs in the line, the telephone company must make the necessary repairs. Responsible instrument manufacturers should provide necessary modification to minimize RFI.

Telephone interference may be cured by connecting a bypass capacitor (about 0.01  $\mu$ F) across the microphone unit in the telephone handset. Telephone companies have capacitors for this purpose, but will only service their own instruments. When such a case occurs, get in touch with the repair department of the phone company, giving the particulars. If you have purchased your instrument from the phone company, you will be billed for the service call if the warranty has expired. Section 500-150-100 of the Bell System Practices *Plant Series* gives detailed instructions; for the General Telephone System, refer to General System Practices *Engineering — Plant Series* Section 471-150-200. This section discusses causes and cures of telephone interference from radio signals. It points out that interference can come from corroded connections, unterminated loops and other sources. It correctly points out that the RF can be picked up on the drop wire coming into the house, and also on the wiring within the house, but the RF detection usually occurs inside the telephone instrument. The detection usually takes place at the varistors in the compensation networks, and/or at the receiver noise suppressor and the carbon microphone.

But interference suppression should be handled two ways: Prevent the RF from getting to the phone, and prevent it from being rectified.

AT&T markets RF filter modules that plug into modular telephone jacks. Model Z100A, for desk phones, is available at local AT&T phone centers (stock number SKU-52610). A second filter, the Z101A for wall-mounted telephones, is available only by mail from the AT&T National Service Center in St. Louis, Missouri (tel 800-222-3111). The stock number for the Z101A is SKU-57293.

#### **Additional Information**

In response to the many hundreds of thousands of RFI-related complaints it has received in recent years, the FCC has produced a booklet designed to show how to solve common RFI problems before they become serious. Entitled *How to Identify and Resolve Radio-TV Interference Problems*, it is available for \$5 from the Government Printing Office, Washington, DC 20402. Make your check payable to "Superintendent of Documents." The ARRL publication, *Radio Frequency Interference*, which sells for \$3, covers all aspects of RFI and includes the complete FCC booklet.

Additional information can be found in the sources listed below.

*Consumer Electronics Service Technician Interference Handbook — Audio Rectification* (Washington, DC: CES, n.d.)\*

*Consumer Electronics Service Technician Interference Handbook — Television Interference* (Washington, DC: CES, n.d.)\*

Nelson, W. R., *Interference Handbook* (Wilton, CT: Radio Publications, 1981).

\*Single copies of the interference handbooks for audio rectification and television interference may be obtained by writing to: Director of Consumer Affairs, Consumer Electronics Group, Electronic Industries Association, 2001 Eye St., N.W., Washington, DC 20006.

# Printed-Circuit Board Etching Patterns

The following pages contain printed-circuit-board etching patterns for the projects in this book. All patterns are full size and are shown from the foil side. Black areas represent unetched copper. The companion parts layout for each pattern is shown with the project description.

More information on making PC boards may be found in Chapter 24. A list of suppliers of PC board and related

materials may be found in Chapter 35.

In the interest of making best use of the space available, the patterns are not arranged in the same order the projects appear in the book. The contents list that follows will help you locate the pattern(s) for your project. In addition, each pattern is clearly labeled with the chapter and figure number of the parts-placement diagram.

## Etching Pattern Contents

<i>Project Name</i>	<i>Chapter</i>	<i>Fig. no. of parts-placement guide</i>	<i>Etching Pattern Page</i>
A Digital TR Sequencer for Satellite Work .....	23	26	17
An IC Voltmeter .....	25	12	4
A 500-MHz Frequency Counter .....	25	30, 32,	3
		34	4
A Simple Inductance Meter .....	25	45	3
An AF/RF Signal Injector .....	26	6	4
Crystal-Controlled Signal Source .....	26	7	4
A 5-A Switching Supply .....	27	5	5
An RF-Proof 30-Amp Supply .....	27	10	5
A 28-V, High-Current Power Supply ..	27	18	9
A 1.2- to 15-Volt, 5-Ampere Supply ..	27	23	5
A Multiple-Voltage Bench Supply .....	27	31	6, 7
A Smorgasbord Supply .....	27	37, 40	9
		43	10
		58	7
The AA6PZ Power Charger .....	27		
A Controlled Battery Charger for Emergency Power Supplies .....	27	61	10
Emergency Gelled-Electrolyte Battery Pack .....	27	68	7
A 2000-Volt Power Supply .....	27	72	8
An Audio Amplifier with AGC for Simple Receivers .....	28	15	5
An Expandable Headphone Mixer .....	28	18	6
An ATV Monitoring Instrument .....	28	22	10
A Simple CMOS Iambic Keyer .....	29	2	6
CW on a Chip .....	29	4	7
BOB — An RS-232-C Break-out Box ..	29	15	12
An LSI Modem for Amateur Radio .....	29	21	13
160-Meter Linear QSK Transverter .....	30	26, 27	15
A VXO-Controlled Transmitter for 3.5 to 21 MHz .....	30	50	13
TR Time-Delay Generator .....	31	22	6
Three-Watt Transmitting Converter for 6 Meters .....	31	38	8
A 2-kW PEP Amplifier for 50 to 54 MHz .....	31	96	16
A Medium-Power 144-MHz Amplifier ..	31	106	18
A Legal-Limit 2-Meter Tetrode Amplifier .....	31	146	11
GaAsFET Preamplifier for 70 cm .....	32	6	16
A 1296- to 144-MHz Transverter .....	32	65, 69	7
		74	10

<i>Project Name</i>	<i>Chapter</i>	<i>Fig. no. of parts-placement guide</i>	<i>Etching Pattern Page</i>
1296-MHz Solid-State Power			
Amplifiers .....	32	78	15
A Homemade DTMF Encoder .....	34	2	16
A PIN Diode TR Switch .....	34	18	14, 17
Digital PEP Wattmeter and			
SWR Calculator .....	34	27	10
		28	9
		29	11
		30	11
A Simple DTMF Decoder	34	7	17
A Marker Generator for 100, 50 and			
25 kHz .....	34	66	18

**CAUTION:**

Thoroughly check the printed pattern before you begin. In case of broken traces, continuity can be restored with a fine-point pen. Any ink bridges can be removed by careful scraping with a sharp, thin knife. Take time to be sure that these potential problems do not exist before you begin — it can save you much time later.

The scraping and drawing techniques described above for knife and pen can also be used to modify or customize patterns. If you feel uneasy, practice on a photocopy to sharpen your skill.

# Abbreviations List

*These abbreviations, revised to conform with contemporary electronics and communications standards, appear in League publications.*

a — atto (prefix for  $10^{-18}$ )  
 A — ampere (unit of electrical current)  
 ac — alternating current  
 ACC — Affiliated Club Coordinator  
 ACSSB — Amplitude-compandored single sideband  
 A/D — analog-to-digital  
 ADC — analog-to-digital converter  
 AF — audio frequency  
 AFC — automatic frequency control  
 AFSK — audio frequency-shift keying  
 AGC — automatic gain control  
 Ah — ampere hour  
 AIRS — ARRL Interference Reporting System  
 ALC — automatic level control  
 AM — amplitude modulation  
 AMTOR — Amateur Teleprinting Over Radio  
 ANT — antenna  
 ARA — Amateur Radio Association  
 ARC — Amateur Radio Club  
 ARES — Amateur Radio Emergency Service  
 ARQ — Automatic repeat request  
 ARS — Amateur Radio Society (Station)  
 ASCII — American National Standard Code for Information Interchange  
 ASSC — Amateur Satellite Service Council  
 ATC — Assistant Technical Coordinator  
 ATV — amateur television  
 AVC — automatic volume control  
 AWG — American wire gauge  
 az-el — azimuth-elevation

B — bel; blower  
 balun — balanced to unbalanced (transformer)  
 BC — broadcast  
 BCD — binary-coded decimal  
 BCI — broadcast interference  
 Bd — baud (bit/s in single-channel binary data transmission)  
 BER — bit error rate  
 BFO — beat-frequency oscillator  
 bit — binary digit  
 bit/s — bits per second  
 BM — Bulletin Manager  
 BPF — band-pass filter  
 BPL — Brass Pounders League  
 BT — battery  
 BW — bandwidth

c — centi (prefix for  $10^{-2}$ )  
 C — coulomb (quantity of electric charge); capacitor

CAC — Contest Advisory Committee  
 CATVI — cable-television interference  
 CB — Citizens Band (radio)  
 CBMS — computer-based message system  
 CCTV — closed-circuit television  
 CCW — coherent CW  
 ccw — counterclockwise  
 CD — civil defense  
 cm — centimeter  
 CMOS — complementary-symmetry metal-oxide semiconductor  
 coax — coaxial cable  
 COR — carrier-operated relay  
 CP — code proficiency (award)  
 CPU — central processing unit  
 CRT — cathode-ray tube  
 CT — center tap  
 CTCSS — continuous tone-coded squelch system  
 cw — clockwise  
 CW — continuous wave

d — deci (prefix for  $10^{-1}$ )  
 D — diode  
 da — deca (prefix for 10)  
 D/A — digital-to-analog  
 DAC — digital-to-analog converter  
 dB — decibel (0.1 bel)  
 dBi — decibels above (or below) isotropic antenna  
 dBm — decibels above (or below) 1 milliwatt  
 DBM — doubly balanced mixer  
 dBV — decibels above/below IV (in video, relative to 1 V P-P)  
 dBW — decibels above/below 1 watt  
 dc — direct current  
 D-C — direct conversion  
 DEC — District Emergency Coordinator  
 deg — degree  
 DET — detector  
 DF — direction finding; direction finder  
 DIP — dual in-line package  
 DPDT — double-pole double-throw (switch)  
 DPSK — differential phase-shift keying  
 DPST — double-pole single-throw (switch)  
 DS — direct sequence (spread spectrum); display  
 DSB — double sideband  
 DTMF — dual-tone multifrequency  
 DVM — digital voltmeter  
 DX — long distance; duplex  
 DXAC — DX Advisory Committee  
 DXCC — DX Century Club

E — voltage  
 e — base of natural logarithms (2.71828)  
 EC — Emergency Coordinator

ECAC — Emergency Communications Advisory Committee  
 ECL — emitter-coupled logic  
 EHF — extremely high frequency (30-300 GHz)  
 EIRP — effective isotropic radiated power  
 ELF — extremely low frequency  
 EMC — electromagnetic compatibility  
 EME — earth-moon-earth (moonbounce)  
 EMF — electromotive force  
 EMI — electromagnetic interference  
 EMP — electromagnetic pulse  
 EPROM — erasable programmable read-only memory

f — femto (prefix for  $10^{-15}$ ); frequency  
 F — farad (capacitance unit); fuse  
 FAX — facsimile  
 FD — Field Day  
 FET — field-effect transistor  
 FL — filter  
 FM — frequency modulation  
 FSK — frequency-shift keying  
 ft — foot (unit of length)

g — gram (unit of mass)  
 G — giga (prefix for  $10^9$ )  
 GaAs — gallium arsenide  
 GDO — grid- or gate-dip oscillator  
 GHz — gigahertz  
 GND — ground

h — hecto (prefix for  $10^2$ )  
 H — henry (unit of inductance)  
 HF — high frequency (3-30 MHz)  
 HFO — high-frequency oscillator  
 HPF — highest probable frequency; high-pass filter  
 Hz — hertz (unit of frequency)

I — current, indicating lamp  
 IC — integrated circuit  
 ID — identification; inside diameter  
 IF — intermediate frequency  
 IMD — intermodulation distortion  
 in — inch (unit of length)  
 in/s — inch per second (unit of velocity)  
 I/O — input/output  
 IRC — international reply coupon  
 ITF — Interference Task Force

j — operator for complex notation, as for reactive component of an impedance (+j inductive; -j capacitive)  
 J — joule ( $\text{kg m}^2/\text{s}^2$ ) (energy or work unit); jack  
 JFET — junction field-effect transistor

k — kilo (prefix for  $10^3$ ); Boltzmann's constant ( $1.38 \times 10^{-23} \text{ J/K}$ )

K — kelvin (used without degree symbol) (absolute temperature scale); relay  
kBd — 1000 bauds  
kbit — 1024 bits  
kbit/s — 1000 bits per second  
kbyte — 1024 bytes  
kg — kilogram  
kHz — kilohertz  
km — kilometer  
kV — kilovolt  
kW — kilowatt  
kΩ — kilohm

l — liter (liquid volume)  
L — lambert; inductor  
lb — pound (force unit)  
LC — inductance-capacitance  
LCD — liquid crystal display  
LED — light-emitting diode  
LF — low frequency (30-300 kHz)  
LHC — left-hand circular (polarization)  
LO — local oscillator; League Official  
LP — log periodic  
LS — loudspeaker  
LSB — lower sideband  
LSI — large-scale integration

m — meter; milli (prefix for 10<sup>-3</sup>)  
M — mega (prefix for 10<sup>6</sup>); meter  
mA — milliamperes  
mAh — millamperehour  
MDS — Multipoint Distribution Service; minimum discernible (or detectable) signal  
MF — medium frequency (300-3000 kHz)  
mH — millihenry  
mho — mho (use siemens)  
MHz — megahertz  
mi — mile, statute (unit of length)  
mi/h — mile per hour  
mi/s — mile per second  
mic — microphone  
min — minute (time)  
MIX — mixer  
mm — millimeter  
MOD — modulator  
modem — modulator/demodulator  
MOS — metal-oxide semiconductor  
MOSFET — metal-oxide semiconductor field-effect transistor  
MS — meteor scatter  
ms — millisecond  
m/s — meters per second  
MSI — medium-scale integration  
MUF — maximum usable frequency  
mV — millivolt  
mW — milliwatt  
MΩ — megohm

n — nano (prefix for 10<sup>-9</sup>)  
NBFM — narrow-band frequency modulation  
NC — no connection; normally closed  
NCS — net-control station; National Communications System  
nF — nanofarad  
NF — noise figure  
nH — nanohenry  
NiCd — nickel cadmium

NM — Net Manager  
NMOS — N-channel metal-oxide silicon  
NO — normally open  
NPN — negative-positive-negative (transistor)  
NR — Novice Roundup (contest)  
ns — nanosecond  
NTS — National Traffic System

OBS — Official Bulletin Station  
OD — outside diameter  
OES — Official Emergency Station  
OO — Official Observer  
op amp — operational amplifier  
ORS — Official Relay Station  
OSC — oscillator (schematic diagram abbrev.)  
OTC — Old Timer's Club  
OTS — Official Traffic Station  
oz — ounce (force unit, 1/16 pound)

p — pico (prefix for 10<sup>-12</sup>)  
P — power; plug  
PA — power amplifier  
PAM — pulse-amplitude modulation  
PC — printed circuit  
PEP — peak envelope power  
PEV — peak envelope voltage  
pF — picofarad  
pH — picohenry  
PIA — Public Information Assistant  
PIN — positive-intrinsic-negative (transistor)  
PIO — Public Information Officer  
PIV — peak inverse voltage  
PLL — phase-locked loop  
PM — phase modulation  
PMOS — P-channel (type) metal-oxide semiconductor  
PNP — positive-negative-positive (transistor)  
pot — potentiometer  
P-P — peak to peak  
ppd — postpaid  
PRAC — Public Relations Advisory Committee  
PROM — programmable read-only memory  
PSHR — Public Service Honor Roll  
PTO — permeability-tuned oscillator  
PTT — push to talk

Q — figure of merit (tuned circuit); transistor  
QRP — low power (less than 5-W output)

R — resistor (schematic diagram abbrev.)  
RACES — Radio Amateur Civil Emergency Service  
RAM — random-access memory  
RC — resistance-capacitance  
R/C — radio control  
RCC — Rag Chewers' Club  
RF — radio frequency  
RFC — radio-frequency choke  
RFI — radio-frequency interference  
RHC — right-hand circular (polarization)  
RIT — receiver incremental tuning

RLC — resistance-inductance-capacitance  
RM — rule making (number assigned to petition)  
r/min — revolution per minute  
RMS — root mean square  
ROM — read-only memory  
r/s — revolution per second  
RST — readability-strength-tone  
RTTY — radioteletype  
RX — receiver, receiving

s — second (time)  
S — siemens (unit of conductance); switch  
SASE — self-addressed stamped envelope  
SEC — Section Emergency Coordinator  
SET — Simulated Emergency Test  
SGL — State Government Liaison  
SHF — super-high frequency (3-30 GHz)  
SM — Section manager; silver mica (capacitor)  
S/N — signal-to-noise (ratio)  
SPDT — single-pole double-throw (switch)  
SPST — single-pole single-throw (switch)  
SS — Sweepstakes; spread spectrum  
SSB — single sideband  
SSC — Special Service Club  
SSI — small-scale integration  
SSTV — slow-scan television  
STM — Section Traffic Manager  
SX — simplex  
sync — synchronous, synchronizing  
SWL — shortwave listener  
SWR — standing-wave ratio

T — tera (prefix for 10<sup>-2</sup>); transformer (schematic diagram abbrev.)  
TA — Technical Advisor  
TC — Technical Coordinator  
TCC — Transcontinental Corps  
TD — Technical Department (ARRL HQ)  
tfc — traffic  
TR — transmit/receive  
TTL — transistor-transistor logic  
TTY — teletypewriter  
TV — television  
TVI — television interference  
TX — transmitter, transmitting

U — integrated circuit  
UHF — ultra-high frequency (300 MHz to 3 GHz)  
USB — upper sideband  
UTC — Coordinated Universal Time  
UV — ultraviolet

V — volt; vacuum tube (schematic diagram abbrev.)  
VCO — voltage-controlled oscillator  
VCR — video cassette recorder  
VDT — video-display terminal  
VE — Volunteer Examiner  
VEC — Volunteer Examiner Coordinator  
VFO — variable-frequency oscillator

VHF — very-high frequency  
(30-300 MHz)  
VLF — very-low frequency (3-30 kHz)  
VLSI — very-large-scale integration  
VMOS — vertical metal-oxide  
semiconductor  
VOM — volt-ohm meter  
VOX — voice operated switch  
VR — voltage regulator  
VRAC — VHF Repeater Advisory  
Committee  
VSWR — voltage standing-wave ratio  
VTVM — vacuum-tube voltmeter  
VUAC — VHF/UHF Advisory  
Committee  
VUCC — VHF/UHF Century Club  
VXO — variable crystal oscillator

W — watt ( $\text{kg m}^2\text{s}^{-3}$ , unit of power)  
WAC — Worked All Continents  
WARC — World Administrative Radio  
Conference  
WAS — Worked All States  
WBFM — wide-band frequency  
modulation  
Wh — watthour  
WPM — words per minute  
WVDC — working voltage, direct  
current

X — reactance  
XCVR — transceiver  
XFMR — transformer  
XO — crystal oscillator  
XTAL — crystal  
XVTR — transverter

Y — crystal (schematic diagram  
abbrev.)  
YIG — yttrium iron garnet

Z — impedance; also see UTC

5BDXCC — Five-Band DXCC  
5BWAC — Five-Band WAC  
5BWAS — Five-Band WAS  
6BWAC — Six-Band WAC

° — degree (plane angle)  
°C — degree Celsius (temperature)  
°F — degree Fahrenheit (temperature)  
 $\alpha$  — (alpha) angles; coefficients,  
attenuation constant, absorption  
factor, area, common-base forward  
current-transfer ratio of a bipolar  
transistor  
 $\beta$  — (beta) angles; coefficients, phase  
constant current gain of common-  
emitter transistor amplifiers  
 $\gamma$  — (gamma) specific gravity, angles,  
electrical conductivity, propagation  
constant  
 $\Gamma$  — (gamma) complex propagation  
constant  
 $\delta$  — (delta) increment or decrement,  
density angles  
 $\Delta$  — (delta) increment or decrement  
determinant, permittivity  
 $\epsilon$  — (epsilon) dielectric constant,  
permittivity, electric intensity  
 $\zeta$  — (zeta) coordinates, coefficients  
 $\eta$  — (eta) intrinsic impedance,  
efficiency, surface charge density,  
hysteresis, coordinate

$\theta$  — (theta) angular phase displacement,  
time constant, reluctance, angles  
 $\iota$  — (iota) unit vector  
K — (kappa) susceptibility, coupling  
coefficient  
 $\lambda$  — (lambda) wavelength, attenuation  
constant  
 $\Lambda$  — (lambda) permeance  
 $\mu$  — (mu) permeability, amplification  
factor, micro (prefix for  $10^{-6}$ )  
 $\mu\text{C}$  — microcomputer  
 $\mu\text{F}$  — microfarad  
 $\mu\text{H}$  — microhenry  
 $\mu\text{P}$  — microprocessor  
 $\xi$  — (xi) coordinates  
 $\pi$  — (pi) 3.14159  
 $\rho$  — (rho) resistivity, volume charge  
density, coordinates, reflection  
coefficient  
 $\sigma$  — (sigma) surface charge density,  
complex propagation constant,  
electrical conductivity, leakage  
coefficient, deviation  
 $\Sigma$  — (sigma) summation  
 $\tau$  — (tau) time constant, volume  
resistivity, time-phase displacement,  
transmission factor, density  
 $\phi$  — (phi) magnetic flux, angles  
 $\Phi$  — (phi) summation  
 $\chi$  — (chi) electric susceptibility, angles  
 $\psi$  — (psi) dielectric flux, phase  
difference, coordinates, angles  
 $\omega$  — (omega) angular velocity  $2\pi f$   
 $\Omega$  — (omega) resistance in ohms, solid  
angle

# INDEX

[Editor's Note: Except for commonly used phrases and abbreviations, topics are indexed by their noun name. Many topics are also cross-indexed, especially when noun modifiers appear (such as "voltage amplifier" and "amplifier, voltage"). For topics having extended coverage, only the first page of presentation is listed. Numerous terms and abbreviations pertaining to Amateur Radio but not contained in this index may be found in the glossaries indexed herein.]

- A-1 Operator Club: 38-13

  - Canadian: 38-7
  - Relationship with TV channels: 40-16
  - US: 38-6
- Amateur beacon stations: 22-12
- Amateur Radio:
  - Becoming licensed: 36-1, 36-2
  - Code: 10
  - Computer Networking Conferences: 19-24
  - History: 1-2, 18-1, 19-1, 19-13, 19-24, 21-14, 23-3
  - Message forms: 38-16
- Operating: 36-1
- Public service: 1-3, 38-14
- Public Service, operating aids: 38-15
- Research and Development Corp.: 21-14
- Station equipment (see Equipment, station)
- Technical developments: 1-3
- Amateur television (see ATV, FSTV and SSTV)
- American National Standard Code for Information Interchange (see ASCII)
- American Radio Relay League (see ARRL)
- Ampere: 2-2
- Amplification factor: 5-3
- Amplifiers:
  - Audio, IC: 4-41
  - Audio, transistor: 4-21
  - Audio, with AGC: 28-6
  - Broadband: 11-10, 12-12
  - Cascade: 5-5
  - Cascode: 12-14
  - Cathode follower: 5-8
  - Circuit symptoms and faults: 26-19
  - Classes of operation: 3-17, 5-4, 5-5, 5-6, 15-1
  - Combined DBM/IF: 12-23
  - Cooling: 15-15
  - Design, guidelines and examples: 15-18, 15-21, 15-22
  - Differential, transistor: 4-19
  - Distortion: 26-10
  - For 144 MHz, medium power: 15-21
  - For 6 meters using the 3CX800A7: 31-31
  - For HF, broadband solid state: 15-22
  - For HF, high power vacuum tube: 15-18
  - Gain: 3-15, 26-9
  - Gain control: 7-5
  - Grounded grid: 5-8
  - High power, for 220 MHz: 31-54
  - IF: 12-26
  - Impedance matching: 15-2
  - Instability, at low frequencies: 15-24
  - Legal limit, 1.8 to 30 MHz: 30-50
  - Legal-limit tetrode for 2 meters: 31-57
  - Low noise: 12-12
  - Medium power, for 144 MHz: 31-39
  - MOSFET: 12-14
  - Neutralization: 15-24
  - Noise: 26-9
  - Operational: 4-41
  - Operational, IC, specifications: 35-23
  - Operational, Norton: 4-43
  - Oscillations: 26-10
  - Output filtering: 15-9
  - Overloading: 12-13
  - Parallel: 5-5
  - Power: 5-4
  - Push-pull: 5-5
  - Push-pull, broadband: 4-25
  - Quarter kilowatt for 23 cm: 32-41
  - RF: 12-9, 12-12, 12-13
  - RF and IF, FET: 4-32
  - RF and IF, IC: 4-38
  - RF power: 15-1
  - RF power, bibliography: 15-25
  - RF power, transistor: 4-22, 4-23
  - Sample-and-hold: 8-23
  - Solid state vs. vacuum tube: 15-1
  - Solid-state for 1296 MHz: 32-37
  - Speech: 7-4
  - Speech, construction: 7-5
  - Speech, driver and output stages: 7-6
  - Speech, op amp: 7-4
  - Stability: 12-12
  - Stabilization: 15-23
  - Tank circuits: 15-3
  - Transformer-coupled: 5-5
  - Transistor: 4-19
  - Triode: 3-14
  - Troubleshooting: 26-9
  - Two kW PEP, for 144 MHz: 31-51
  - Two kW PEP, for 50 MHz: 31-35
  - Vacuum tubes: 5-2
  - VHF: 12-13, 12-15
  - Video transmitters: 20-3
  - Voltage: 5-4, 7-5
  - 3CX800A7 for 144 MHz: 31-46
  - 1500-W 3CX1200A7: 30-58
  - 1500-W output for 160 meters: 30-46
- Amplitude companded SSB: 7-9, 9-6, 18-1, 18-17
- Amplitude modulation (see Modulation, amplitude)
- Amplitude noise: 10-18
- AMRAD: 21-14
- AMSAT: 1-3
- AMSAT-OSCAR 8: 21-3
- AMSAT-OSCAR 9: 21-4, 23-3
- AMSAT-OSCAR 10: 23-2, 23-3
  - (also see OSCAR)
- Band plan: 23-2
- AMSAT-OSCAR 13: 23-1, 23-2
- AMTOR: 19-13, 21-6
  - Bibliography: 19-14
  - Mode A: 19-14
  - Mode B: 19-14
  - Operating: 19-14, 38-9
- Analog switch ICs: 8-22
- Analog telephony: 9-5
- Analog-to-digital conversion (see Digital and analog interfacing)
- Analysis, of single-tuned circuits: 3-6
- Analyzers, spectrum: 25-41
- Anchoring:
  - Antenna supports: 37-20
  - Guy anchors: 37-21
- Angle:
  - Conduction: 5-6
  - Modulation: 9-3
  - Of radiation: 17-2
- Annie, program for plotting antenna patterns: 17-3
- Anode: 5-1
- Antennas: 17-1
  - (also see Arrays)
  - Accessories, satellite: 23-18
  - Annie, program for plotting patterns: 17-3
  - As loads: 16-4
  - Assembling: 37-19
  - ATV: 20-3
  - Bandwidth: 17-2
  - Beams, 2- and 3-element: 17-15
  - Beams, construction of: 33-4
  - Choice of: 17-1
  - Circular polarization: 23-5
  - Conductor size: 17-3
  - Correcting imbalance: 39-9
  - Current and voltage distribution: 17-3, 17-7
  - Decoupling: 14-3
  - Delta loops: 17-17
  - Diameter vs. length: 17-3
  - Dipoles, bent: 17-6
  - Dipoles, helically wound: 17-6
  - Dipoles, trap: 17-6
  - Dipoles, trap, portable: 33-6
  - Directivity: 17-8
  - Drooping dipole: 17-5
  - Dummy: 25-22, 26-4, 34-22, 34-24
  - EME: 23-33
  - Feed methods: 17-4
  - Feedhorn with circular polarization: 23-23
  - Ferrite rod: 39-2
  - FMTV: 20-10
  - Folded dipoles: 16-6
  - Folded unipole: 17-12
  - Gain: 17-7, 17-18
  - Gain vs. spacing: 17-15
  - Ground plane, for VHF and UHF: 33-29
  - Height: 17-1
  - Helical, for 432 MHz: 33-27
  - Impedance: 17-1, 17-2, 17-7
  - Impedance matching: 17-19
  - Installation: 37-28
  - Installation, PVRC mount: 37-30
  - Insulators: 33-2
  - Length of 1/2 wavelength: 17-3
  - Long wire: 17-7
  - Loop: 39-1
  - Loop Yagis for 23 cm: 32-54
  - Loop, with sensing element for 28 MHz: 39-11
  - Loopstick for 1.8 MHz: 39-12
  - Loopstick for 3.5 MHz: 39-13
  - Marconi: 17-11
  - Matching: 33-15
  - Matching to transmission lines: 16-3
  - Minooka Special: 17-12
  - Mobile, 220 MHz, 5/8 wave: 33-29
  - Mobile, HF: 33-15
  - Noise bridge: 25-33
  - Parabolic, Mode L: 23-21
  - Parasitic excitation: 17-15
  - Polarization: 17-1, 17-18

**Antennas (continued)**

Portable:	33-6, 33-14
Portable, considerations:	37-37, 37-38
Portable, for 144 MHz:	33-22
Projects:	33-1
Quad, triband:	33-12
Quads:	17-14, 17-17
Quagi, VHF:	33-25
Radial networks:	17-13
Radiation angle of:	17-2
Radiation characteristics:	17-3
Raising:	37-29
Random length, coupling to:	16-9
RDF:	39-1, 39-8, 39-10, 39-11, 39-12, 39-13, 39-14, 39-15
Repeater:	14-8
Rod:	39-2
Rotation, electronic:	39-5
Rotator systems:	37-31
Rotators for satellite work:	23-13
Routing cables:	37-16
Satellite:	23-10, 23-21
Sensing:	39-2
Stacking of Yagis:	17-20
Supports:	37-19, 37-20
Top loading:	33-17
TR switching:	19-8
Trap verticals:	17-14
Troubleshooting:	26-13
Tuner (see Transmatch)	
Tuning adjustments:	17-16
TV, installation:	40-14
UHF:	17-18
Vertical:	17-10
Vertical, 144 MHz, 5/8 wave:	33-28
Vertical, a 2-band:	33-10
Vertical, construction of:	33-4
Vertical, short:	17-12
Vertical, VHF 1/4 wave:	33-27
Verticals, trap, adapting to WARC bands:	33-11
VHF:	17-18
Wire, construction:	33-1
Wire, supporting:	37-19
With driven elements:	17-8
Wullenweber:	39-5
Yagi:	17-14
Yagi, 432 MHz, 15 elements:	33-24
Yagi, 50 MHz, 5 elements:	33-21
Yagi, dimensions for 50-432 MHz:	33-19
Yagi, two band, optimum gain:	33-13
Yagi, VHF and UHF:	33-18
Zepp:	17-5
1/2 sloper:	17-13
1/2 wavelength:	17-3
Anticyclone (high-pressure system):	22-17
Apparent power:	2-26
Application layer:	19-45
APT:	20-23
Arcing:	26-13
ARES:	38-15
Arithmetic logic unit:	8-27
ARQ:	19-13
Arrays:	
Adcock:	39-3, 39-15
Broadside:	17-9
Collinear:	17-8, 17-21
Combined types:	17-10
End fire:	17-9
Phased:	39-3
Phased, for 144 MHz RDF:	39-14
ARRL:	1-2, 1-4
Amateur Radio Computer Networking	
Conferences:	19-24
Contests:	38-14
Digital Communications Committee:	19-23
Field organization:	1-4, 40-4
HQ station W1AW:	38-16
International involvement:	1-6
Leadership:	1-4
Membership:	1-6
Membership services:	1-5
Parts suppliers list:	35-38
Publications:	1-4
QSL Bureau:	38-1
RFI immunity complaint reports:	40-3
ASCII:	19-14, 21-6
Amateur RTTY operations:	19-17

Bibliography:	19-17
Code extensions:	19-16
Control characters:	19-15
Data rates:	19-16
Operating:	38-9
Parity:	19-16
Serial transmission:	19-16
Assembly language:	8-33
Assembly, antennas:	37-19
Asynchronous communications:	8-18
Asynchronous data transmission:	19-16
Atom:	2-1, 4-45
Attenuation:	2-37
Of twisted wire pairs:	3-13
Attenuators:	12-11
Attenuators, step, low power:	25-37
ATV:	20-1, 21-6
Antennas for:	20-3
Monitoring instrument:	28-8
Operating:	38-5
Receivers for:	20-3
Receiving preamp and converter:	20-4
Repeaters:	20-4
Transmission lines:	20-3
Transmitters:	20-3, 20-4
Audio:	7-1
Amplifier with AGC:	28-6
Filters:	28-1, 28-3
Frequency shift keying:	9-11, 19-12
Noise limiters:	12-32
Peak filters:	13-11
Phasing networks:	18-8
Transmission, for FSTV:	20-4
Audio frequencies (AF):	2-5
Audio memory keyer:	29-19
Aurora:	22-7, 22-12, 22-13, 22-15
Authentication:	21-6
Automatic gain control (see AGC)	
Automatic level control:	7-8
Autopatch:	14-14
Autostart, RTTY:	19-13
Autotransformers:	2-32
Average voltage:	2-12
Average vs. peak power:	18-13
Awards:	1-2
A-1 Operator Club:	38-13
Code Proficiency:	38-13

Carrier operated relay (COR):	14-9	Capacitors:	35-1	Construction:	
Cascade amplifiers:	5-5	Hookup wire:	35-5	Antenna projects:	33-1
Cascade amplifier:	12-14	Power transformer leads:	35-3	Beam antennas:	33-4
Cathode:	5-1, 5-2	Resistors:	35-1	Boards, perforated:	24-10
Bias:	3-16, 5-9	Color perception:	7-11	Materials:	24-2
Follower:	5-8	Color SSTV:	20-16, 20-17	Power supply projects:	27-1
Keying:	19-5	Color TV:	7-17, 20-2	Techniques:	3-1

**Construction (continued)**

Vertical antennas:	33-4	Quartz:	2-53	Dibit modulation:	19-17
Consumer electronic devices:		Switching of:	10-3, 11-2	Dielectric constant:	2-13
Frequencies used in:	40-4	CTCSS:	14-15	And breakdown voltages:	2-13
Radiation limits:	40-3	Cubical quad (see Antennas, quad)		Dielectric loss:	3-2
Contesting:	38-13	Cup cores:	2-32	Differential amplifiers:	4-19
Contests:	1-2, 38-14	Current:	2-2	Differential keying:	19-7
Continuous tone coded squelch system (CTCSS):	14-15	And electric fields:	2-3	Diffraction:	22-18
Control:		Density:	2-3	Digipeaters:	19-42
Error:	21-5	Distribution, in antennas:	17-3, 17-7	Digital:	
Key:	8-30	Plate:	5-2	Bibliography:	8-36
Of repeaters:	14-9, 14-13	Regulator diodes:	4-16	Binary systems:	8-1
Of repeaters, with microprocessors:	14-14	Sink:	2-4	Equipment troubleshooting:	26-15
Radio:	21-1	Source:	2-4	ICs (see ICs, digital)	
Troubleshooting:	26-12	Current limiting:		Noise:	8-35
Unit, digital computer:	8-27	Foldback:	6-16	PEP wattmeter:	34-10
Wires, on towers:	17-13	In voltage regulators:	6-15	To-analog conversion (see Digital and analog interfacing)	
Conversion factors, metric:	8, 9	Cutoff frequency:	2-39	TR sequencer:	23-20
Conversion, single:	12-9	Cutting holes:	24-4	Voice recorder:	29-19
Conversions, time:	38-2	Cutting sheet metal:	24-5	Digital and analog interfacing:	
Converters:		CW:	9-8	Aliasing:	8-21
(also see Mixers)		Coherent:	21-16	Nyquist Sampling Theorem:	8-21
ATV:	20-4	Filters:	28-1	Sampling rate:	8-21
Interdigital, for 1296 or 2304 MHz:	32-10	Keyer, deluxe memory:	29-13	Sampling resolution:	8-22
Scan, SSTV:	20-15	Keyer, microprocessor-based memory:	29-6	Signal-to-noise ratio:	8-22
Transmitting, 3 W, for 50 MHz:	31-13	Keyer, simple CMOS:	29-1	Digital communications:	19-1
Cooling:		Keyer, single IC:	29-4	Baseband encoding techniques:	19-39
Transistors:	15-17	Operating:	38-4	Committee, ARRL:	19-23
Vacuum tubes:	15-15	Reception:	28-1	Glossary of terminology:	19-48
Coordinated Universal Time (UTC):	38-2	Transmitters for:	11-2	Packet radio:	19-23
Coordinates:		Cycle:	2-4	Procedures:	38-8
Converting between polar and rectangular:	2-25	D/A converter:	8-21	Regulatory changes:	19-1
Polar:	2-24	Data communications:	9-12	Digital computer:	8-26
Rectangular:	2-24	Data interfaces:		Arithmetic logic unit (ALU):	8-27
Coordination, repeaters:	14-16	Full-duplex:	19-31	Control unit:	8-27
Copper wire, table:	35-6	Half-duplex:	19-31	Display:	8-30
Copperweld wire:	33-1	Operational modes:	19-30	Floppy disk:	8-29
COR (carrier operated relay):	14-9	Simplex:	19-30	Hard disk:	8-29
Cordwood modules:	24-13	Data rate:	8-19	Input device:	8-26
Cores:		Datagram protocol:	19-44	Input/output (see Input/output)	
A, values:	2-34	dB:	2-7	Interrupt:	8-28
High permeability:	3-8	dBm:	2-7, 12-21, 12-23	Keyboard:	8-30
Iron, inductors:	2-20	dB $\mu$ V:	2-7	Languages:	8-33
Material, transformers:	2-31	dBV:	2-7	Memory (see Computer memory)	
Permeability:	2-33	dBW:	2-7	Monitor:	8-30
Physical properties:	2-34	Dc:	2-4	Operating systems:	8-34
Types, inductors and transformers:	2-32	Meters:	25-1, 25-3	Organization of subsystems:	8-26
Corona:	2-3	To-dc conversion:	6-23	Output device:	8-27
Correlation, spread spectrum:	21-10	Dead-bug construction:	24-11	Peripheral devices:	8-28
Coulomb:	2-1	Decibel:	2-7	Printer:	8-32

Test equipment for:	20-11				
Transmitters for:	20-8				

Holes:		Mutual:	2-21	Joule:	2-1, 2-12
Drilling and cutting:	24-4	Of a straight wire:	2-18	Junction FET (see Transistors, JFET)	
Rectangular:	24-4	Of a wire above a ground plane:	2-19		
Hopping, frequency (FH spread spectrum):	21-9	Parallel:	2-20	Key clicks:	19-5
Hopping, time:	21-9	Series:	2-20	Keyboard:	8-30
Horsepower:	2-11	Inductive reactance:	2-22, 2-38, 2-51	Keys:	
Hot carrier diodes:	4-6	Inductors:	26-22	Audio memory:	29-19
Hum:	12-8	At VHF:	2-18	Deluxe Memory:	29-13
Filament:	5-9	Coefficient of coupling:	2-21	Memory:	29-6
Hybrid combiner for signal generators:	25-37	Coupled:	2-21	Microprocessor-based memory:	29-6
Hybrid digital meters:	25-5	Current as a function of time:	2-21	Simple CMOS:	29-1
Hysteresis:	2-30	Distributed capacitance of:	2-18	Single chip:	29-4
In squelch circuits:	14-10	Energy storage:	2-21	Keying:	
Iron-core inductors:	2-20	Equivalent circuit of:	3-3	Audio frequency shift:	9-11
Hz (hertz):	2-5	Iron-core, eddy currents:	2-20	Blocked grid:	19-5
		Iron-core, hysteresis:	2-20	Cathode:	19-5
I/O (see Input/Output)		Iron-core, permeability of:	2-20	Circuits:	19-7
IARU:	1-6	Iron-core, saturation of:	2-20	Differential:	19-7
ICs:		Laminations in iron-core:	2-20	Frequency shift:	9-10, 19-12
Am7910 single-chip modem:	29-30	Mutually coupled:	2-52	Minimum shift:	9-13, 19-32
Analog switch:	8-22	Number of turns:	2-34	Monitor:	19-9
Array:	4-37	Skin effect:	2-18	On-off:	9-8, 19-12
Audio amplifiers:	4-41	Infinite impedance detectors:	18-11	Oscillator:	19-7
Bilateral switch:	8-22	Injection:		Phase shift:	19-32
CMOS:	4-37	Signal:	26-17	Troubleshooting:	26-13
Composition of:	4-36	Stages:	12-20	Kilowatt-hour:	2-12
Frequency synthesizers:	10-17	Injectors, signal:	26-6	Kirchhoff's First Law:	2-9
Linear:	4-36	AF and RF:	26-5	Kirchhoff's Second Law:	2-10
Mixers:	4-40, 12-17	Input impedance:	5-8	Klystrons:	5-10
Modulators, balanced:	18-4	Input/Output:		Knife-edge diffraction:	22-18
Op amps, base diagrams:	35-24	Handshaking:	8-19		
Op amps, specifications:	35-23	Memory-mapped:	8-28	Lacing cables:	24-7
RF and IF amplifiers:	4-38	Parallel:	8-19	Ladder networks:	2-37, 2-53
Single-chip CW keyer:	29-4	Polled:	8-28	Lambert conformal conic projection:	39-8
Subsystems:	4-38	Program-controlled:	8-28	Lamps, miniature, specifications:	35-30
TTL, specifications:	35-33	Serial:	8-21	Land breezes:	22-18
Voltage regulators:	6-17	Insertion loss:	2-37	Latch (see Flip-flop)	
IDC (insulation displacement connector):	37-15	Instability:		Leadership, ARRL:	1-4
Identification:		In oscillators:	12-10	Leads, test:	26-2
Repeater:	14-10	Low frequency, in amplifiers:	15-24	Leakage:	
Station:	38-8	Installation:		Flux:	2-30
IF:		Antennas:	37-28	Inductance:	2-30
Amplifiers:	12-23, 12-26	Antennas, PVRC mount:	37-30	Reactance:	2-30
Choice of:	12-26	Towers:	37-26	RF:	3-1
Derived AGC:	12-10	Insulation displacement connectors:	37-15	LED:	4-13
Filters, receiver:	12-9	Insulators:	4-45	Legal-limit 2-meter tetrode amplifier:	31-57
Interference:	40-12	Antenna:	33-2	Length vs. diameter, antennas:	17-3
Noise silencers:	12-32	Integrated circuits (see ICs)		Lenses:	7-15
Passband tuning:	13-5	Interdigital converters, for 1296 or		F stops:	7-16
Port:	12-22	2304 MHz:	32-10	Letter-quality printer:	8-32
Responses, wideband:	12-24	Interelectrode capacitance:	5-7	Libration fading:	23-29
Selectivity:	12-26	Interfacing external devices:	8-17	License:	
Shift tuning:	13-5	Interfacing logic families:		Amateur Radio:	36-1, 36-2
IFM (incidental frequency modulation):	10-20	CMOS to ECL:	8-15	Study classes:	36-3
Image:		CMOS to TTL:	8-13	Light, velocity of:	2-6
Communications:	9-7, 20-1	ECL to CMOS:	8-15	Light-emitting diode (LED):	4-13
Processing, FAX:	20-19	ECL to TTL:	8-15	Lightning arrestor:	2-3
Response:	12-23	TTL to CMOS:	8-13	Lightning protection:	37-3
Imaginary numbers:	2-24	TTL to ECL:	8-14	Limitless detectors, RTTY:	19-12
IMD (intermodulation distortion):	14-8	Using optocouplers:	8-16	Limiters:	18-22
Test, two tone, receivers:	25-40	Interference (also see RFI and TVI):	40-1	Noise:	12-31
Impedance:	2-24	Interference, intersymbol:	19-17	Line-of-sight propagation:	22-15
Characteristic:	16-1, 16-12	Intermediate frequency (see IF)		Linear:	
Complex:	2-24	Intermodulation distortion (see IMD)		Approximations, of nonlinear devices:	3-14
Complex notation for:	2-24	Intermodulation intercept point, mixers:	12-24	Baluns:	16-7
Imaginary component of:	2-24	International Amateur Radio Union (IARU):	1-6	ICs:	4-36
Magnitude of:	2-24	International Sunspot Number (ISN):	22-5	Translators:	14-16
Matching (also see Matching and		International Telecommunication Union (ITU):	1-6	Transverters for 144 and 220 MHz:	31-17
Transmatches):	2-31, 33-15	International Telegraph and Telephone		Voltage regulators:	6-14
Matching networks:	2-53	Consultative Committee (CCITT):	19-10	Link budget:	
Of antennas:	17-1, 17-2, 17-7	Interpreter:	8-33	Calculations:	23-6
Of twisted wire pairs:	3-13	Interrupt-driven I/O:	8-28	Satellites:	23-6
Ohm's Law:	2-25	Inverted V antennas (see Dipole, drooping)		Link coupling:	3-5

Logic buffer:		Measurement, US units of:	8	Mixers:	12-14
Inverting (see Logic gates, NOT)		Measurements:	25-1	Active:	12-15
Noninverting:	8-3	Ac:	25-7	Balanced:	12-16, 12-17, 12-19, 12-21
Logic families:		Ac waveform:	2-12	Comparisons of types:	12-21
Bipolar:	8-10	Dc:	25-1	Diode:	4-6
Comparing:	8-9, 8-12	Deviation:	18-21	Diode ring:	12-15
Emitter-coupled Logic (ECL):	8-11	Distortion:	26-10	Doubly balanced:	12-21, 12-23
Fan-out:	8-9	Distortion, interpreting:	18-15	FET:	4-33, 12-16
Impedance:	8-9	Frequency:	25-11, 25-13	For headphones:	28-7
Interfacing (see Interfacing logic families)		IMD, receivers:	25-40	HF:	12-16
Metal-oxide semiconductor (MOS):	8-12	Nonsinusoidal waves:	25-7	High level:	11-6
Power consumption:	8-9	Power:	25-3	IC:	4-40, 12-17
Speed:	8-9	Receiver noise figure:	12-3	Intermodulation intercept point:	12-24
Transistor-transistor logic (TTL):	8-10	Receiver performance:	25-39	Noise figure:	12-24
Logic gates:		Resistance:	25-3	Performance:	12-15
AND:	8-2	RF power:	25-9	Selection of:	12-23
Exclusive NOR:	8-3	RF voltage:	25-9	Terminology:	12-24
Exclusive OR:	8-3	RMS:	25-7	Transistor:	4-27
NAND:	8-3	Sine waves:	25-7	Transmitting:	11-6
NOR:	8-3	Spectrum analyzer:	25-41	UHF:	12-18
NOT:	8-2	SWR:	25-10	VHF:	12-18
OR:	8-2	Voltage:	25-2	MMIC (monolithic microwave integrated circuit):	32-24
Polarity:	8-3	Measuring phase noise:	10-22	Mobile antennas:	33-15, 33-29
XNOR:	8-3	Mechanical filters:	12-27	Mobile operation:	1-2
XOR:	8-3	Membership services, ARRL:	1-5	Mobile stations:	37-32
Logic polarity:	8-3	Membership, ARRL:	1-6	Charging system noise:	37-33
Long wire antennas:	17-7	Membrane keyboard:	8-30	Corona discharge:	37-33
Long-path propagation:	22-8	Memory, computer (see Computer memory)		Electrical noise elimination:	37-33
Loop:		Memory-mapped I/O:	8-28	Electrical noise reduction:	37-34
Antennas:	39-1	Message forms, amateur:	38-16	Instrument noise:	37-33
Circuits, RTTY:	19-11	Message systems, computer based (CBMS):	38-10	Spark plug noise:	37-33
Filter:	10-11	Metal gauges:	24-6	Modems:	
Phase-locked:	10-11	Meteor scatter:	22-12, 22-13, 22-15	Bell 103:	19-34
Shielded, with sensing antenna, for		Packet radio:	19-25	Bell 202:	19-34
28 MHz:	39-11	Meteor showers, prominent annual:	22-15	Eye patterns:	19-38
Yagis for 23 cm:	32-54	Meters:		LSI, for Amateur Radio:	29-30
Loopstick antennas:		Ac:	25-7	Packet radio:	19-31, 19-36
For 1.8 MHz:	39-12	Dc:	25-1	Parameters:	19-32
For 3.5 MHz:	39-13	Deviation:	18-21	RTTY:	19-12
Losses:		Dip:	26-4	Standards:	19-34
Dielectric:	3-2	Electronic voltmeters:	25-5	Testing:	19-37
In transmission lines:	16-14	Field strength, portable:	39-10	Modern filters:	2-41
Loudspeakers:	7-11	Frequency:	26-6	Modes, spacecraft:	23-1
Low-level computer languages (see Computer languages)		Hybrid digital:	25-5	Modulated CW:	9-10
Low-pass filter:	2-39, 11-8	IC voltmeter:	25-5	Modulation:	9-1
Lowest usable frequency (LUF):	22-2, 22-3, 22-7	Linearity:	25-8	Amplitude:	9-2, 18-1
LSB:	9-1, 9-3	Multipliers:	25-2	Angle:	9-3
		Ohmmeters:	25-3	Cross:	40-12, 40-17
		Rectifier type:	25-7	Dibit:	19-17
Magnetic field:	2-17	RMS:	25-7	Format, FAX:	20-20, 20-21
Of the Earth:	22-7	Shunts:	25-2	Four-phase:	19-17
Magnetic path:	2-31	Signal strength:	12-30	Frequency:	9-3, 18-18
Magnetic properties, toroid cores:	35-5	SWR:	26-3, 34-9, 34-10	Image communications:	9-7
Magnetism:	2-1	Thermocouple:	25-7	Index:	9-3
Magnetizing current:	2-30	Voltage:	25-2, 25-3	Multilevel:	9-13
Manuals, equipment, sources of:	26-2	Voltmeter impedances:	25-8	Phase:	9-3, 18-18
Maps (also see Projections):		Voltmeters, electronic, RF probe for:	25-9	Pulse:	9-4
For RDF:	39-6, 39-8	Metric:		Spin, satellites:	23-6
Marconi antennas:	17-11	Conversion factors:	8, 9	Systems:	9-2, 9-4
Marker generator:	25-11	Equivalents:	35-36	Modulator/demodulator:	19-12
For 100, 50 and 25 kHz:	34-30	Prefixes:	2-5	Modulators:	
Masts:		System:	2-1	Balanced:	18-3
Protection:	37-21	Mica capacitors:	26-22	Balanced IC:	18-4
Simple wooden:	37-20	Microcomputer (see Digital computer)		Phase:	18-19
Matching (also see Impedance matching and Transmatches):	11-10	Microfarad ( $\mu$ F):	2-14	Reactance:	18-19
Amplifier impedances:	15-2	Microhenrys ( $\mu$ H):	2-17	Modules:	
Antenna impedances:	17-19	Microphones:	7-2	Cordwood:	24-13
Antennas:	33-15	Carbon:	7-3	Thick film:	24-13
Antennas to transmission lines:	16-4	Ceramic:	7-4	Monimatch circuits:	25-10
Balanced QRP:	34-19	Crystal:	7-3	Monitoring:	
Broadband transformers:	15-7	Directivity:	7-3	ATV:	28-8
Circuits for transmission lines:	16-10	Dynamic:	7-4	Keying:	19-9
Delta match:	17-19	Electret:	7-4	Volunteer:	3

Mounting plate, universal:	33-11	Numbers:		Oscilloscopes:	25-27, 26-4
MS DOS:	8-35	Complex:	2-24	Digital:	25-30
MSK (minimum shift keying):	9-13, 19-32	Imaginary:	2-24	Lissajous figures:	25-31
MUF (maximum usable frequency):	22-7, 22-10, 22-12, 22-13	NVRAM:	8-26	Narrow bandwidth, HF adapter for:	25-32
Multihop propagation:	22-3	Nylon, properties of:	35-33	Probes:	25-29
Multilevel modulation:	9-13	Nyquist rate:	8-21	Storage scopes:	25-31
Multimeters:	26-2	Nyquist sampling theorem:	8-21	OSI reference model:	19-26
Multiplexing:	21-5	Object program:	8-33	Output filtering:	11-6
Frequency division:	21-5	Ohm:	2-7	Output impedance:	5-8
Time division:	21-5	Ohm's Law:	2-3, 2-8, 2-21	Output power, low:	26-13
Multiplication, frequency:	11-4	For reactance:	2-22	Overdamped wave:	10-11
Multiplier stages:	12-20	Impedance:	2-25	Overhead, in asynchronous communications:	8-19
Multipliers, meter:	25-2	Ohmmeters:	25-3	Overloading:	12-13
Multivibrator:		Old Timers Club:	38-13	Overtone oscillators:	10-2
Astable:	8-8	On-off keying (OOK):	9-8, 19-12		
Bistable (see Flip-flop)		One-shot multivibrator:	8-8	P-P voltage:	2-12
Duty cycle:	8-9	Op amps:	4-41	Packet Radio:	19-23
Free-running:	8-8	As audio filters:	7-10	Application layer:	19-45
Monostable:	8-8	As speech amplifiers:	7-4	Assembler/disassemblers:	19-42
One-shot:	8-8	IC, base diagrams:	35-24	AX.25:	19-24, 19-30
555 IC:	8-9	IC, specifications:	35-23	Bibliography:	19-45
Mutual coupling:	2-52	Norton:	4-43	Bulletin boards:	19-25
Mutual inductance:	2-21, 2-29	Open Systems Interconnection Reference Model (OSI-RM):	19-26	Channel access:	19-40
Mutual reactance:	2-52	Operating:		Circuit turnaround time:	19-40
		Aids for public service:	38-15	Datagram protocol:	19-44
National Electrical Code:	37-2	AMTOR:	19-14, 38-9	Digipeaters:	19-42
National Traffic System (NTS):	38-15	ASCII:	38-9	History:	19-24
Negative logic:	8-3	ASCII RTTY:	19-17	Meteor scatter:	19-25
Negative-lead filtering:	6-10	ATV:	38-5	Modems:	19-31, 19-36
Nets, traffic:	1-2	CW:	38-4	NET.EXE:	19-45
Network:		EME:	23-32	NET/ROM:	19-45
Active:	3-13	FSTV:	38-5	Network layer:	19-43
Audio phasing:	18-8	Hints, voice:	38-3	Network protocol:	19-44
Dissipationless:	2-37	ITA2:	38-8	Networking:	19-45
Equations for:	11-12	Mobile:	1-2	On HF:	19-25
Ladder:	2-37, 2-53	Packet radio:	38-10	Periodicals:	19-46
Ladder, solving problems:	2-38	Practices, phone:	38-3	Presentation layer:	19-44
Layer:	19-43	Repeaters:	38-3	Product sources:	19-47
Matching:	2-38, 2-53	RTTY:	38-8	Protocols:	19-40, 38-10
Matching, frequency response:	2-54	SSTV:	20-15, 38-8	Satellites:	23-3
Matching, link coupled:	34-17	Standards:	38-1	Session layer:	19-44
Nonlinear:	3-13	Operational amplifiers (see Op amps)		Seven OSI layers, The:	19-26, 19-40
Protocol:	19-44	Optical shaft encoder:	8-16	Teleports:	19-25
RF phasing:	18-8	Optics, TV cameras:	7-15	TEXNET:	19-46
Synthesis:	2-39	Optocoupler:	8-16	Transport layer:	19-44
Neutralization:		Optoisolator:	8-16	Virtual-circuit networking:	19-46
Amplifiers:	15-24	Organs, RFI:	40-18	Virtual-circuit protocol:	19-44
Screen grid tubes:	15-25	OSCAR satellites (also see AMSAT-OSCAR):	1-2, 1-3, 21-4, 21-4, 23-1	PACSAT:	19-24, 19-26, 23-3
Neutron:	2-1	OSCAR 8:	21-3	Padder capacitors:	10-5
Newton:	2-1	OSCAR 9:	21-4, 23-3	Paper capacitors:	26-22
Newton-meter (joule):	2-1	OSCAR 10:	23-2, 23-3	Parabolic antenna for Mode L:	23-21
Noise:		Band plan:	23-2	Parallel:	
Amplitude:	10-18	OSCAR 11:	23-3	Amplifiers:	5-5
Automotive:	37-33, 37-34	OSCAR 12:	23-2	And series circuit equivalents:	2-25
Blankers:	12-31	OSCAR 13:	23-1, 23-2	Circuit impedance:	2-25
Bridge, for 160 through 10 Meters:	25-33	Oscillations:		Circuit resonance:	2-27
Cancellation, microphones:	7-3	Parasitic:	10-2, 15-23	Interface:	8-19
Digital:	8-35	Oscillator phase noise:	10-18	Resonance in low-Q circuits:	2-28
Elimination, mobile stations:	37-33	Oscillator-multiplier transmitters:	11-5	Signaling:	8-17
Factor:	12-2	Oscillators:	3-16, 12-20	Parallel-resonant circuit:	
Figure:	12-2	AF:	25-21	Equivalent series-resonant circuit:	2-25
Gated source:	25-32	AF, wide range:	25-21	Parasitic excitation, antennas:	17-15
Ground:	37-5	Beat-frequency:	12-10, 12-29	Parasitic oscillations:	10-2
Impulse:	12-31	Colpitts:	10-1, 10-2	VHF and UHF:	15-23
In oscillators:	12-10	Crystal:	10-1, 11-2, 25-11	Parity:	8-19, 21-6
Limiters:	12-31	Crystal controlled signal source:	26-5	Parts suppliers list:	35-38
Phase:	10-9, 10-18	Crystal, adjusting frequency of:	10-2	Pascal:	8-34
Power:	12-2	Crystal, FET:	4-34	Passband tuning:	13-5
Prevention:	8-35	Crystal, for VHF:	12-20	Passive filters:	28-1, 28-3
Reduction:	12-30	Crystal, variable frequency:	10-3	Path loss, satellites:	23-6
Temperature:	12-2	For code practice:	36-6	PC boards:	
VFOs:	10-8	Hartley:	10-4	Etching:	24-9
Noise figure:		Instability:	12-10, 26-11	Fabrication:	24-9
Measurements:	12-3	Keying:	19-7	Nonetched:	24-10
Mixers:	12-24	Local:	12-10	Planning and layout:	24-9
Noise floor measurement, receivers:	25-40	Modified Pierce:	10-2	Utility:	24-10
Noninverting logic buffer:	8-3	Noise in:	12-10	Peak:	
Nonlinear devices, linear approximations of:	3-14	Overtone:	10-2	Envelope power (PEP):	2-13
Norton operational amplifier:	4-43	Pierce:	10-1	Envelope voltage (PEV):	2-12

Levels in amateur equipment:	10-21	Fusing:	6-1	Selected VHF/UHF references:	22-18
Measuring:	10-22	Voltage:	6-1	Short-path:	22-8
Measuring transmitter:	10-23	Power supplies:	6-1, 26-6	Sidescatter:	22-9
Oscillator:	10-18	Battery eliminator for FM portables:	27-27	Sporadic-E:	22-2, 22-10, 22-12
Specifying levels:	10-19	Connector standard:	27-1	Transequatorial spread-F (TE):	22-14
Typical maximum tolerable levels:	10-21	Construction projects:	27-1	Tropospheric ducting:	22-16
Phase-locked loop (see PLL)		Economy:	6-11	Tropospheric enhancement:	22-16
Phased arrays:	39-3	Filters:	6-7	Tropospheric scatter:	22-12, 22-16
144 MHz RDF:	39-14	Load resistance:	6-7	VHF, UHF, Microwave:	22-12
Phase-shift keying (PSK):	19-32	Multiple voltage bench supply:	27-16	1.8-MHz (160-meter):	22-9
Phasing method of generating SSB:	18-8	Perfect 10:	27-27	3.5-MHz (80-meter):	22-10
Phasing networks:		Primary circuit:	27-1	7-MHz (40-meter):	22-10
Audio:	18-8	Regulation for CW keying:	19-4	10-MHz (30-meter):	22-10
RF:	18-8	Safety:	27-1	14-MHz (20-meter):	22-10
Phenolics, properties:	35-33	Smorgasbord supply:	27-19	18-MHz (17-meter):	22-10
Phone operating practices:	38-3	Solar:	6-28	21-MHz (15-meter):	22-10
Phonetics:	38-4	Thermal design:	6-18	24-MHz (12-meter):	22-10
Physics of solid-state devices:	4-45	Troubleshooting:	26-8	28-MHz (10-meter):	22-10
Pi networks:	15-6	1.2- to 15-V, 5-A supply:	27-12	50-54 MHz (6-meter):	22-12
Pi-L networks:	15-6	5- to 25-V, 5-A deluxe supply:	27-12	144-148 MHz (2-meter):	22-12
Picofarad (pF):	2-14	5-A switching supply:	27-1	220-225 MHz (135-cm):	22-12
Picture transmission:	7-12	28-V, high current:	27-9	420-450 MHz (70-cm):	22-13
Picture tubes:	7-17	30-A, RF proof supply:	27-3	Propagation delay:	16-1
Pierce oscillators:	10-1	2000-V, 1-A supply:	27-37	Protection:	
Modified:	10-2	3500-V, 1-A supply:	27-39	Lightning:	37-3
Piezoelectric crystals:	2-53	Power-to-voltage conversion table:	35-37	Receiver front end:	12-14
Pilot tone:	18-17	Pre-emphasis:	9-3	Protocols, packet radio:	38-10
PIN diodes:	4-11	Preamble, spread spectrum:	21-12	Proton:	2-1
TR switch:	34-6	Preamplifiers:		Prototype boards, solderless:	24-10
Planck's constant:	4-45	Audio, and RFI:	40-17	PSK (phase-shift keying):	19-32
Plastic film capacitors:	26-22	Cost effective, for 1296 MHz:	32-6	Public address systems, RFI:	40-18
Plastics, properties:	35-33	Dual-gate GaAsFET for 1296 MHz:	32-5, 32-7	Public Law 97-259:	40-2, 40-3
Plate:	5-1	Dual-gate GaAsFET for 28, 50, 144 and 220 MHz:	31-3	Public service:	1-3, 38-14
Current:	5-2	Dual-gate GaAsFET for 432 MHz:	32-1	Operating aids:	38-15
Detectors:	18-11	FET:	12-14	Publications, ARRL:	1-4
Mounting, universal:	33-11	For satellite work:	23-9	Pulleys:	37-22
PLL:	10-11, 10-17, 10-18	GaAsFET for 144 and 220 MHz:	31-5	Pulse modulation:	9-4
Demodulators:	18-25	GaAsFET for 432 MHz:	32-3	Pulse, binary, digital (see Digital pulse)	
PL tones:	14-15	MOSFET, for 28, 50, 144 and 220 MHz:	31-1	Pulses:	
PN junctions:	4-46	Remote switching system:	31-6	Blanking:	7-14
Polar coordinates:	2-24	Prescaler, dual modulus:	10-16	TV Synchronization:	7-14, 20-2
Converting to rectangular:	2-25	Presentation layer:	19-44	Push-pull amplifiers:	4-25, 5-5
Polarity, logic:	8-3	Primary current:	2-30	PVC, properties:	35-33
Polarization:		Printer:	8-32	PVRC mount, antenna installation:	37-30
Circular:	17-22	Printers, RTTY:	19-10	Q (Quality factor):	2-27
Of antennas:	17-1, 17-18	Probes, oscilloscope:	25-29	Of a tuned circuit:	12-3
Poles, gin:	37-23	Procedures:		Of loaded circuits:	2-28
Polyethylene, properties:	35-33	Communications:	38-2	Section:	16-4, 16-5
Polypropylene, properties:	35-33	Digital communications:	38-8	Signals:	38-5
Polystyrene, properties:	35-33	Processing, image:	20-19	Tank circuits:	15-5
Port:		Processing, speech:	7-6	Unloaded:	2-27
IF:	12-22	SSB:	7-7	QEX:	1-5
LO:	12-22	Product detectors:	18-11	QSL:	
RF:	12-22	Active:	18-12	Bureau:	1-6, 38-1
Termination:	12-22	Program counter:	8-27	Cards:	38-1
Portable:		Programmable dividers:	10-12, 10-12, 10-15, 10-17	QST:	1-5
Antennas:	33-6, 33-14, 33-22	Programs:		Quad antennas:	17-14, 17-17
Field strength meter:	39-10	For determining az-el of celestial bodies:	23-30	Triband:	33-12
144-MHz antenna:	33-22	MINIMUF:	22-10	Quadrifilar windings:	24-8
Portable stations:	37-34	Project OSCAR:	1-3	Quagi antennas, VHF:	33-25
Ac power sources:	37-34	Projections:		Quarter kilowatt amplifier for 23 cm:	32-41
Antenna considerations:	37-37	Azimuthal equidistant:	39-8	Quartz crystals:	2-53
Position indicator, rotators:	23-15	Gnomonic:	39-8	Radial networks:	17-13
Positive logic:	8-3	Lambert conformal conic:	39-8	Radiation:	
Pot cores:	2-32	PROM:	8-26	Angle:	17-2, 22-7

		220-MHz high power amplifier:	31-54
		220-MHz preamplifier, dual-gate GaAsFET:	31-3
		220-MHz preamplifier, GaAsFET:	31-5
		220-MHz preamplifier, MOSFET:	31-1
		220-MHz transverter:	31-17
		220-MHz Yagi antenna dimensions:	33-19
		420-450 MHz (70-cm) propagation:	22-13
		420-MHz antennas:	
		Ground plane:	33-29
		432-MHz antennas:	
		Helical:	33-27
		432-MHz preamplifiers:	32-1, 32-3
		432-MHz Yagi antenna dimensions:	33-19
		432-MHz Yagi antenna, 15 elements:	33-24
		500-MHz frequency counter:	25-13
		1296- to 144-MHz Transverter:	32-24
		1296-MHz antennas:	32-54
		1296-MHz filter, 3 elements:	32-18
		1296-MHz interdigital converter:	32-10
		1296-MHz preamplifiers:	32-5, 32-6
		1296-MHz quarter-kilowatt amplifier:	32-41
		1296-MHz solid-state power amplifiers:	32-37
		1296-MHz transverter:	32-14
		2304-MHz interdigital converter:	32-10
		2800-MHz solar flux:	22-6, 22-13
